Abstract

We performed new large-scale ^{12}CO , ^{13}CO , and C^{18}O $J=1-0$ observations of the W43 giant molecular cloud complex in the tangential direction of the Scutum arm ($l \sim 30^\circ$) as a part of the FUGIN project. The low-density gas traced by ^{12}CO is distributed over $150 \text{ pc} \times 100 \text{ pc}$ ($l \times b$),

and has a large velocity dispersion (20-30 km s⁻¹). However, the dense gas traced by C¹⁸O is localized in the W43 Main, G30.5, and W43 South (G29.96-0.02) high-mass star-forming regions in the W43 GMC complex, which have clumpy structures. We found at least two clouds with a velocity difference of ~ 10 -20 km s⁻¹, both of which are likely to be physically associated with these high-mass star-forming regions based on the results of high ¹³CO $J = 3-2$ to $J = 1-0$ intensity ratio and morphological correspondence with the infrared dust emission. The velocity separation of these clouds in W43 Main, G30.5, and W43 South is too large for each cloud to be gravitationally bound. We also revealed that the dense gas in the W43 GMC has a high local column density, while the current SFE" of entire the GMC is low ($\sim 4\%$) compared with the W51 and M17 GMC. We argue that the supersonic cloud-cloud collision hypothesis can explain the origin of the local mini-starbursts and dense gas formation in the W43 GMC complex.

Key words: ISM: HII regions — ISM: clouds — ISM: molecules — stars: formation — ISM: individual objects (W43, W43 Main, G30.5, W43 South, G29.96-0.02)

1 Introduction

1.1 Giant molecular clouds and mini-starbursts in the Milky Way

Giant molecular clouds (GMCs), whose masses are $\gtrsim 10^4 M_{\odot}$ (e.g., Blitz 1993), have been studied by CO surveys of the Milky Way using single-dish radio telescopes since the 1970s (e.g., Dame et al. 1986, 2001; Solomon et al. 1987; Scoville et al. 1987; Mizuno & Fukui 2006; see also reviews of Combes 1991; Heyer & Dame 2015). Recently, high-angular-resolution CO surveys have revealed the internal structures of GMCs using the Nobeyama 45-m (FUGIN: Umemoto et al. 2017), JCMT 15 m, (COHRS: Dempsey et al. 2015, CHIMPS: Rigby et al. 2017), PMO 13.7 m (MWISP: Su et al. 2019), and Mopra 22 m (Burton et al. 2013; Braiding et al. 2018) telescopes. GMCs have ideal environments, with massive and dense gas, for the formation of high-mass stars and cluster formation (e.g., Lada & Lada 2003; McKee & Ostriker 2009), and their evolution and formation mechanism has been widely studied in the Milky Way and Local Group Galaxies (e.g., Blitz et al. 2007; Fukui & Kawamura 2010). In particular, massive GMCs often form aggregations called GMC complexes", which are regarded as sites for mini-starbursts including O-type stars (e.g., W43, W49, W51, Sagittarius B2, NGC 6334-6357: see a review of Motte et al. 2018a). On the other hand, it is not yet clear how high-mass stars and natal massive dense cores are formed in GMCs (e.g., Gao and Solomon 2004; Lada et al. 2012; Torii et al. 2019).

1.2 The initial condition of O-type star formation produced by a supersonic cloud-cloud collision

To form the O-type stars ($> 20 M_{\odot}$), it is necessary to achieve high mass accretion at the rate of $\sim 10^{-3} M_{\odot} \text{ yr}^{-1}$ (e.g., Wolfire & Cassinelli 1987) to overcome their strong radiation pressure. Zinnecker & Yorke (2007) argued that rapid external shock compression" such as the supersonic gas motions might be an important initial condition for O-type star formation.

Cloud-cloud collisions have been discussed as one of the external triggering mechanisms that produce gravitational instability and high-mass star formation (e.g., Scoville et al. 1986; Elmegreen 1998). Recently, observational evidence has been presented of many super star clusters and O-type star-forming regions in the Milky Way. For example,

- Super star clusters (young massive clusters): Compact distributions of O-type stars in 1 pc
Westerlund 2 (Furukawa et al. 2009; Ohama et al. 2010), NGC 3603 (Fukui et al. 2014), RCW 38 (Fukui et al. 2016), etc.
- Multiple O-type star formation in the GMCs
Sagittarius B2 (Hasegawa et al. 1994; Sato et al. 2001), W49A (Mufson & Liszt 1977; Miyawaki et al. 1986; 2009), W51A (Okumura et al. 2001; Kang et al. 2010; Fujita et al. 2019b), NGC 6334-6357 (Fukui et al. 2018a), M17 (Nishimura et al. 2018), M42 (Fukui et al. 2018d), RCW 79 (Ohama et al. 2018a), W33 (Kohno et al. 2018a), DR21 (Dobashi et al. 2019), etc.
- Single O-type star formation in mid-infrared bubbles and H II regions
M20 (Torii et al. 2011,2017), RCW 120 (Torii et al. 2015), N37 (Baug et al. 2016), Sh2-235 (Dewangan & Ojha 2017), N49

(Dewangan et al. 2017), RCW 34 (Hayashi et al. 2018), RCW 36 (Sano et al. 2018), RCW 32 (Enokiya et al. 2018), GM 24 (Fukui et al. 2018b), S116-118 (Fukui et al. 2018c), N35 (Torii et al. 2018a), N36 (Dewangan et al. 2018), Sh 2-48 (Torii et al. 2018b), RCW 166 (Ohama et al. 2018b), S44 (Kohno et al. 2018b), G8.14+0.23 (Dewangan et al. 2019), N4 (Fujita et al. 2019a), etc

Numerical simulations show that gravitationally-unstable, dense cores are formed in the compressed layer of two colliding clouds (e.g., Habe & Ohta 1992; Anathpindika 2010; Takahira et al. 2014, 2018; Balfour et al. 2015, 2017; Matsumoto et al. 2015; Shima et al. 2018; Wu et al. 2015, 2017a, 2017b, 2018). Inoue & Fukui (2013) demonstrated from the results of a magneto-hydrodynamical (MHD) simulation that the shock compression from a collision can produce massive molecular cores by amplifying the turbulence and magnetic field. These massive cores can achieve a high enough accretion rate ($> 10^{-4} M_{\odot} \text{yr}^{-1}$) to form O-type stars (Inoue et al. 2018). Hence, a supersonic cloud-cloud collision is a prominent scenario in which the initial conditions for O-type stars and dense gas formation of galaxies can be met.

In order to clarify the origin of dense gas and O-type star formation in GMC complexes, we have performed a new high-resolution and complete survey in the ^{12}CO , ^{13}CO , and $\text{C}^{18}\text{O } J=1-0$ lines of the entire W43 GMC complex, where active star formation is ongoing. This paper is constructed as follows: section 2 introduces the current knowledge on W43; section 3 presents the observational properties; section 4 gives the FUGIN results and comparisons with infrared wavelengths; in section 5 we discuss the formation mechanism of the W43 GMC complex; and in section 6 we provide the conclusions of this paper.

2 W43 as a massive GMC complex in the Milky Way

W43 is a Galactic mini-starburst region located in Aquila, which was first cataloged by the 1390 MHz thermal radio continuum survey (Westerhout 1958). It is one of the most massive GMC complexes in the Milky Way, corresponding to giant molecular associations (GMA) of external galaxies (Nguyen-Luong et al. 2011). Figure 1(a) shows a three-color composite image obtained by the Spitzer space telescope, where blue, green, and red correspond to the 3.6 μm , 8 μm , and 24 μm emissions, respectively (GLIMPSE: Benjamin et al. 2003; Churchwell et al. 2009; MIPS GAL: Carey et al. 2009). The X-marks indicate W43 Main (Blum et al. 1999) and W43 South (Wood & Churchwell 1989), which are active star forming regions. G30.5 exists between W43 Main and W43 South, which contains five star-forming regions. A 100 pc bow-like structure, vertical to the Galactic plane, was found by the Nobeyama 10 GHz radio continuum survey (Sofue 1985; Handa et al. 1987). The 3.6 μm , 8 μm , and 24 μm emission traces thermal emission from stars, Polycyclic Aromatic Hydrocarbon (PAH) features (e.g., Draine 2003; Draine & Li 2007), and hot dust grains (~ 120 K) excited by the high-mass stars (Carey et al. 2009), respectively. The 8 μm emission shows diffuse distribution covering the whole GMC complex. The 24 μm emission is bright at W43 Main and W43 South, indicating the existence of H II regions. The properties of these objects are described in Table 1.

The distances of W43 South and compact H II regions around G31.5 have been measured by trigonometric parallax, yielding 5.49 kpc as the variance-weighted average of four maser sources of G029.86-00.04, G029.95-00.01, G031.28+00.06, and G031.58+00.07 from the Bar and Spiral Structure Legacy Survey (BeSSeL: Zhang et al. 2014; Sato et al. 2014). In this paper, we assume the same distance (5.49 kpc) toward W43 Main, because it coincides with a near-side kinematic distance of $v_{\text{LSR}} \sim 95$ km s $^{-1}$ at $l \sim 30.^{\circ}8$. Figure 2 shows the position of W43 superposed on the top-view of the Milky Way (R. Hurt: NASA/JPL-Caltech/SSC). We point out that W43 exists close to the tangential point of the Scutum arm (e.g., Vallée 2014; Hou & Han 2014; Nakanishi & Sofue 2016). In addition, this region is suggested to be the meeting point of the Galactic long-bar and the Scutum arm (e.g., Nguyen-Luong et al. 2011; Veneziani et al. 2017). Therefore, W43 is an important object for studying the spiral arm and bar interaction.

Large-scale CO observations of W43 have been performed by single-dish radio telescopes (Nguyen Luong et al. 2011; Carlhoff et al. 2013; Motte et al. 2014). They showed that W43 is a molecular cloud complex with a size of ~ 100 -200 pc, and a broad velocity dispersion of 20-30 km s $^{-1}$. They proposed that a cloud-cloud collision or a colliding flow scenario is likely to explain the origin of the mini-starbursts in the W43 GMC at the tip of the Galactic bar (e.g., Nguyen-Luong et al. 2011, 2013; Motte et al. 2014; Louvet et al. 2016; see also review section 4.3 of Motte et al. 2018a). Furthermore, a number of papers have been published on the W43 GMC complex (e.g., Pipher et al. 1974; Lester et al. 1985; Liszt et al. 1993; Liszt 1995; Mooney et al. 1995; Subrahmanyan & Goss 1996; Balser et al. 2001; Lemoine-Goumard et al. 2011; Beuther et al. 2012; Nishitani et al. 2012; Eden et al. 2012; Moore et al. 2015; Bihr et al. 2015; Walsh et al. 2016; Génova-Santos et al. 2017; Langer et al. 2017; Bialy et al. 2017). On the other hand, these papers do not deal with detail analysis toward individual objects in the W43 GMC complex. In the next subsection, we introduce the individual objects of W43 Main, G30.5, and W43 South, on which we base our analysis.

2.1 W43 Main (G030.8-00.0) as a mini-starburst region in the Milky Way

Figure 1(b) shows a close-up image of W43 Main. The X-mark indicates the center position of an OB cluster (Blum et al. 1999), and the white circles present 51 protocluster candidates identified by sub-millimeter dust continuum observations (Motte et al. 2003). W43 Main is the most active high-mass star-forming region in the W43 GMC complex (e.g., Nguyen-Luong et al. 2013, 2017; Cortes et al. 2019), associated with a giant H II region and a young massive cluster (Blum et al. 1999; Longmore et al. 2014). We find a ring-like structure in 8 μm emission, which corresponds to the infrared bubble N52 (Churchwell et al. 2006). The total infrared luminosity and ultraviolet photon number (N_{UV}) are estimated to be $7 - 10 \times 10^6 L_{\odot}$ (e.g., Hattori et al. 2016; Hanaoka et al. 2019; Lin et al. 2016) and $2.3 \times 10^{50} \text{ s}^{-1}$ from the flux density at 5 GHz (Smith et al. 1978; Deharveng et al. 2010), respectively. The N_{UV} is equivalent to ~ 14 O5V or ~ 40 O7V stars, based on the stellar parameters of Martins et al. (2005). The W43 Main cluster contains one Wolf-Rayet star (W43#1) and two O-type giant stars (W43 #2 and W43 #3), identified by Blum et al. (1999). W43#1 is also listed as WR 121a (van der Hutch 2001). W43 #1 and #3 are likely to be binary O-type stars concentrated in a narrow space of < 1 pc from the W43 Main cluster (Luque-Escamilla et al. 2011; Binder & Povich 2018). Their stellar ages are estimated to be 1–6 Myr, based on the typical main-sequence lives of the O-type stars and Wolf-Rayet stars (Motte et al. 2003; Bally et al. 2010). We summarize the properties of the W43 Main cluster in Table 2.

Recently, several papers have been published on W43-MM1 (e.g., Cortes & Crutcher 2006; Cortes et al. 2010; Cortes 2011; Cortes et al. 2016; Herpin et al. 2012; Sridharan et al. 2014; Louvet et al. 2014; Jacq et al. 2016; Nony et al. 2018; Molet et al. 2019). These papers revealed that W43-MM1 is the most massive protocluster in W43 Main by the interferometer observations. In particular, Motte et al. (2018b) identified 131 massive dust clumps in W43-MM1 from Atacama Large Millimeter/Submillimeter Array (ALMA) observations. They showed that the core mass function (CMF) is flatter (more top-heavy) than the stellar initial mass function (IMF: Salpeter 1955), which suggests that massive dense cores are likely to be formed more efficiently in W43-MM1.

2.2 G30.5

Figure 1(c) shows a close-up image of G30.5, which exists between W43 Main and W43 South. Five star-forming regions exist at G30.5: IRAS 18445-0222, IRAS 18447-0229, G030.489-00.364, G030.213-00.156, and G30.404-00.238 (Beichman et al. 1988; Anderson et al. 2014¹; Lockman 1989). There are 870 μm cold dust clumps corresponding to these infrared sources except for G030.489-00.364 (Nguyen-Luong et al. 2011). They also found multiple velocity components by using the $^{13}\text{CO } J = 1-0$ emission (see Figure 4 of Nguyen-Luong et al. 2011). Recently, Sofue et al. (2019) analyzed the FUGIN data on the W43 GMC complex. They revealed a molecular bow structure in G30.5, which is suggested to be formed by the Galactic shock compression (Fujimoto 1968; Roberts 1969; Tosa 1973). We point out that these star-forming regions correspond to the head of the molecular bow.

2.3 W43 South (G29.96-0.02)

Figure 1(d) presents a close-up image of W43 South (G29.96-0.02). The crosses indicate the radio continuum sources identified by the NRAO/VLA Sky Survey (NVSS: Condon et al. 1998), and correspond to the late-O or early-B type stars from the radio continuum flux (Beltrán et al. 2013). The numbering is the same as in Beltrán et al. (2013). The total luminosity is derived to be $2-6 \times 10^6 L_{\odot}$ (Beltrán et al. 2013, Lin et al. 2016). The stellar age is derived to be ~ 0.1 Myr from the evolutionary stage of the ultra-compact H II region (Watson & Hanson 1997), which is younger than W43 Main. The brightest infrared source (#1=IRAS 18434-0242) is regarded as an ultra-compact H II region or hot core, and has been well studied by many authors (e.g., Pratap et al. 1994, 1999; Afflerbach et al. 1994; Cesaroni et al. 1994, 1998, 2017; Fey et al. 1995; Lumsden & Hoare 1996, 1999; Ball et al. 1996; Watarai et al. 1998; Maxia et al. 2001; De Buizer et al. 2002; Morisset et al. 2002; Martín-Hernández et al. 2003; Olmi et al. 2003; Rizzo et al. 2003; Hoffman et al. 2003; Zhu et al. 2005; Kirk et al. 2010; Beltrán et al. 2011; Pillai et al. 2011; Townsley et al. 2014; Roshi et al. 2017). We summarize the properties of W43 South in Table 3.

Several papers have been published on the W43 GMC complex and its individual clusters, so far a comprehensive study of diffuse molecular clouds and dense cores does not exist. In this paper, we have performed the analysis of ^{12}CO , ^{13}CO , and $\text{C}^{18}\text{O } J = 1-0$ emissions from the W43 GMC complex, obtained from the FUGIN data.

¹ <http://astro.phys.wvu.edu/wise/>

3 Data sets

3.1 The FUGIN project: the Nobeyama 45-m telescope ^{12}CO , ^{13}CO , and C^{18}O $J = 1-0$ observations

We performed the CO $J = 1-0$ survey using the 45-m telescope at the Nobeyama Radio Observatory (NRO). We simultaneously observed the present region in ^{12}CO (115.271 GHz), ^{13}CO (110.201 GHz), and C^{18}O (109.782 GHz) $J = 1-0$ transitions as part of the FUGIN project². The area of inner Galaxy covering $l = 10^\circ-50^\circ$, $b = -1^\circ-1^\circ$ as shown Figure 2 has been surveyed using the on-the-fly (OTF) mapping mode (Sawada et al. 2008) from April 2014 to March 2017 (Minamidani et al. 2015; Umemoto et al. 2017). The front-end consists of four beams, dual polarization, and sideband-separating (2SB) superconductor-insulator-superconductor (SIS) receiver FOur-beam REceiver System on the 45 m Telescope (FOREST: Minamidani et al. 2016, Nakajima et al. 2019), with a typical system noise temperature (T_{sys}) of ~ 250 K (^{12}CO) and 150 K (^{13}CO). The back-end is an FX-type digital spectrometer named Spectral Analysis Machine for the 45 m telescope (SAM45: Kuno et al. 2011), which is the same as the digital spectro-correlator system for the ALMA Atacama Compact Array (Kamazaki et al. 2012). It has 4096 channels with a bandwidth and frequency resolution of 1 GHz and 244.14 kHz, which correspond to 2600 km s^{-1} and 0.65 km s^{-1} at 115 GHz, respectively. The effective velocity resolution is 1.3 km s^{-1} . The half power beam width (HPBW) of the 45 m telescope is $14''$ and $15''$ at 115 GHz and 110 GHz, respectively. The effective beam size of the final data cube, convolved with a Bessel \times Gaussian function, is $20''$ for ^{12}CO and $21''$ for ^{13}CO , corresponding to $\sim 0.5 \text{ pc}$ at a distance of 5.5 kpc. The pointing accuracy is smaller than $2''-3''$, and measured by observing 43 GHz SiO maser sources every hour using the H40 High Electron Mobility Transistor (HEMT) receiver. We used the chopper-wheel method (Ulich & Haas 1976; Kutner & Ulich 1981) to convert to the antenna temperature (T_a^*) scale from the raw data. The data were calibrated to the main-beam temperature (T_{mb}) by using the equation $T_{\text{mb}} = T_a^* / \eta_{\text{mb}}$ with a main beam efficiency (η_{mb}) of 0.43 for ^{12}CO , and 0.45 for ^{13}CO and C^{18}O . The relative intensity uncertainty is estimated at 10–20% for ^{12}CO , 10% for ^{13}CO , and 10% for C^{18}O by observation of the standard source M17 SW (Umemoto et al. 2017). The final 3D FITS cube has a voxel size of $(l, b, v) = (8.''5, 8.''5, 0.65 \text{ km s}^{-1})$. We smoothed the data by convolving it with the two-dimensional Gaussian function ($35''$) to achieve a spatial resolution of $\sim 40''$. The root-mean-square (rms) noise levels after smoothing are ~ 1.0 K, 0.35 K, and 0.35 K for ^{12}CO , ^{13}CO , and C^{18}O , respectively. More detailed information on the FUGIN project, we refer to described by Umemoto et al. (2017).

3.2 The CHIMPS project: JCMT ^{13}CO $J = 3-2$ archive data

We also used the James Clerk Maxwell Telescope (JCMT) archival data of the CO ($J = 3-2$) Heterodyne Inner Milky Way Plane Survey (CHIMPS³) project (Rigby et al. 2016; 2019). The cube data were obtained from the JCMT web page⁴ with an effective resolution of $15''$ obtained by the Heterodyne Array Receiver Program (HARP: Buckle et al. 2009). We carried out the regridding in the spatial and velocity areas with reference to the FUGIN data. We adopted $\eta_{\text{mb}} = 0.72$ as the main beam efficiency (Buckle et al. 2009), and converted the intensity from T_a^* to the T_{mb} scale. The relative intensity uncertainty was estimated within 20 % for ^{13}CO $J = 3-2$ (Rigby et al. 2016). We convolved the data with a $37''$ Gaussian to achieve a spatial resolution of $\sim 40''$. The rms noise level after smoothing was 0.14 K for ^{13}CO $J = 3-2$.

3.3 Spitzer infrared archive data

We used infrared archival data obtained by the Spitzer space telescope (Werner et al. 2004). The near-infrared $3.6 \mu\text{m}$ and $8.0 \mu\text{m}$ images were obtained by the Infrared Array Camera (IRAC: Fazio et al. 2004) as a part of the Galactic Legacy Infrared Midplane Survey Extraordinaire (GLIMPSE) project (Benjamin et al. 2003, Churchwell et al. 2009). The mid-infrared $24 \mu\text{m}$ images were taken from the Multi-band Imaging Photometer for Spitzer (MIPS: Rieke et al. 2004) as a part of the 24 and 70 Micron Survey of the Inner Galactic Disk with MIPS (MIPSGAL) project (Carey et al. 2009). The resolutions of these images are $\sim 2''$, $\sim 2''$, and $\sim 6''$ for $3.6 \mu\text{m}$, $8.0 \mu\text{m}$, and $24 \mu\text{m}$, respectively. We summarize the observational properties and archival information in Table 4.

4 Results

This section is organized as follows: subsection 4.1 presents the CO distribution in the first galactic quadrant; subsection 4.2 gives CO distributions and velocity structures of the W43 GMC complex; and subsections 4.3–4.5 focus on the three regions of W43 Main,

² <https://nro-fugin.github.io>

³ <https://www.eaobservatory.org/jcmt/science/large-programs/chimps2/>

⁴ <http://dx.doi.org/10.11570/16.0001>

G30.5, and W43 South, respectively. These are active star-forming regions in the W43 GMC complex.

4.1 Galactic-scale CO distributions and velocity structures in the first galactic quadrant with FUGIN

The upper panels of Figures 3, 4, and 5 show the integrated intensity maps of the inner Galaxy ($l = 10^\circ\text{--}50^\circ$, $b = -1^\circ\text{--}1^\circ$) of ^{12}CO , ^{13}CO , and C^{18}O , respectively. The integrated velocity ranges from -30 to 160 km s^{-1} . The lower panels show the Galactic longitude-velocity diagrams, where the dotted lines indicate the spiral arm suggested by Reid et al. (2016). We find the Norma, Sagittarius, Scutum, Perseus, Near 3 kpc, Far 3 kpc, and Outer (Cygnus) spiral arms lie in this region of the inner Galactic plane. The Aquila Rift and Aquila Spur are also identified as the local components of the solar neighborhood and the inter-arm region, respectively. The active high-mass star-forming regions and a supernova remnant exist in each spiral arm (e.g., W33, M17, M16, W43, W49, W51, and W44). W43 exists in the Galactic plane in the direction of $l = 30^\circ$, which contains rich gas, as seen in the integrated intensity maps and longitude-velocity diagram of the first quadrant (Figures 3-5). This region is close to the tangential point of the Scutum Arm and the bar-end of the Milky Way (Nguyen-Luong et al. 2011). The ^{13}CO also traces the spiral structures more clearly (Figure 4). We note that dense gas traced by C^{18}O (Figure 5) has localized distribution compared with the low-density gas traced by ^{12}CO (Figure 3).

4.2 CO distributions of the W43 giant molecular cloud complex

Figure 6 demonstrates the integrated intensity maps of the W43 GMC complex, in (a) ^{12}CO , (b) ^{13}CO , and (c) C^{18}O . The integrated velocity ranges from 78 to 120 km s^{-1} , which corresponds to those defined by the previous IRAM CO $J = 2-1$ observations by Carlhoff et al. (2013). The X marks show the center positions of W43 Main and W43 South (Blum et al. 1999; Wood & Churchwell 1989). The entire GMC complex is distributed over $\sim 150\text{ pc}$ of the Galactic plane. The CO intensity has peaks at W43 Main, G30.5, and W43 South. Each region corresponds to a high-mass star-forming region. We point out that the C^{18}O exists locally at W43 Main, G30.5, and W43 South. The C^{18}O is surrounded by the diffuse molecular gas traced by ^{12}CO .

Figures 7, 8, and 9 show velocity channel maps of ^{12}CO , ^{13}CO , and C^{18}O , respectively. The velocity ranges from 66 to 125 km s^{-1} , with an interval of $\sim 4\text{ km s}^{-1}$. The velocity of the peak positions in W43 Main, G30.5, and W43 South ranges between $90\text{--}105\text{ km s}^{-1}$, $100\text{--}109\text{ km s}^{-1}$, and $93\text{--}105\text{ km s}^{-1}$, respectively. We find that the dense gas traced by C^{18}O has clumpy structures over a wide velocity range (Figure 9).

Figure 10 shows the longitude-velocity diagrams integrated over the latitudes between -0.4° and 0.4° . The ^{12}CO has a much larger velocity width ($\sim 20\text{--}30\text{ km s}^{-1}$; Figure 10a, and 11) than is typical for a GMC, with a size of 100 pc ($\Delta v \sim 10\text{ km s}^{-1}$) calculated by Larson's law ($\Delta v \sim R^{0.5}$; Larson 1981; Heyer & Brunt 2004). The velocity width of the ^{13}CO line is narrower than that of ^{12}CO (Figure 10a and 10b). However, C^{18}O has clumpy structures with velocity widths of $< 10\text{ km s}^{-1}$ (Figure 10c), and the large cloud complex in ^{12}CO breaks into multiple velocity components in C^{18}O .

The total molecular masses of the whole W43 GMC are derived from ^{12}CO , ^{13}CO , and C^{18}O to be $\sim 1 \times 10^7 M_\odot$, $\sim 1 \times 10^7 M_\odot$, and $\sim 2 \times 10^6 M_\odot$ above 5σ noise levels ($\sim 5\text{ K}$ of ^{12}CO and 1.75 K of ^{13}CO , $\text{C}^{18}\text{O } J = 1-0$), respectively. Table 5 presents column densities and molecular masses of the W43 GMC complex. The molecular masses estimated from ^{12}CO are roughly consistent with the masses calculated from ^{13}CO . On the other hand, The mass estimation from C^{18}O is a factor of 4 lower than the others. This difference might be caused by the variation of the CO abundance ratio due to the UV radiation from OB-type stars in the W43 GMC complex. According to Bally and Langer (1982), the selective photodissociation occurs in the surface layer of molecular clouds. Because the self-shielding against UV radiation is more efficient for more abundant molecule, dissociation of C^{18}O becomes more effective at low density region, resulting in making the C^{18}O molecule an empirical dense gas tracer. Indeed, Paron et al. (2018) reported that the $^{13}\text{CO}/\text{C}^{18}\text{O}$ abundance ratio ($X^{13/18}$) has low in the dense region of W43 South (G29.96-0.02). We present details of the method calculating the physical properties of the molecular gas in Appendix 1.

Figure 11 shows the spectra of (a) W43 Main, (b) G30.5, and (c) W43 South. We find a large velocity width ($20\text{--}30\text{ km s}^{-1}$) in ^{12}CO and multiple velocity components in ^{13}CO from 80 to 120 km s^{-1} (see red arrows of Figure 11). We observe that the 70 km s^{-1} component is the foreground cloud, as suggested by Carlhoff et al. (2013).

In the next subsection, we present the results of detailed analysis in W43 Main, G30.5, and W43 South, aiming to reveal the origin of the dense gas and high-mass stars.

4.3 W43 Main

4.3.1 ^{13}CO and C^{18}O spatial distributions and velocity structures

We find four clouds at different velocities (82 km s^{-1} , 94 km s^{-1} , 103 km s^{-1} , and 115 km s^{-1}) in the W43 Main cluster. Figure 12 presents integrated intensity maps of each cloud in the ^{13}CO (Figures 12 a-d) and C^{18}O (Figures 12 e-h) emission. The X-mark indicates a stellar cluster, and the white circles show 51 protocluster candidates identified by Motte et al. (2003).

The 82 km s^{-1} cloud (Figures 12a, 12e) has an intensity peak at $(l, b) \sim (30^\circ 66, 0^\circ 03)$, and extends over 20 pc on the western side of the cluster. The 94 km s^{-1} cloud (Figures 12b, 12f) is the brightest component, and is distributed over 20 pc around the cluster. Two peaks in ^{13}CO correspond to the W43-MM1 and W43-MM2 ridges identified in the N_2H^+ and SiO emission (Nguyen-Luong et al. 2013). In particular, the W43-MM2 ridge is brightest in the C^{18}O emission (Figure 12f). The 103 km s^{-1} cloud (Figures 12c, 12g) has intensity peaks at $(l, b) \sim (30^\circ 83, -0^\circ 05)$ and $(l, b) \sim (30^\circ 86, -0^\circ 08)$, $\sim 5 \text{ pc}$ apart from the cluster. These peaks also correspond to the W43-MM1 ridge. The 115 km s^{-1} cloud (Figures 12d, 12h) shows the diffuse component of ^{13}CO near the cluster center. The two peaks exist at $(l, b) \sim (30^\circ 63, -0^\circ 11)$ and $(l, b) \sim (30^\circ 81, -0^\circ 19)$, which is separate from the cluster. We also show the velocity channel maps in the Appendix Figures 26-28

Figure 13 displays the latitude-velocity diagram of W43 Main in (a) ^{13}CO and (b) $\text{C}^{18}\text{O } J=1-0$. The black boxes indicate the radio recombination line (RRL) velocity of 91.7 km s^{-1} at $(l, b) \sim (30^\circ 780, -0^\circ 020)$ obtained by Luisi et al. (2017). The yellow line indicates the position of the W43 Main cluster. The 94 km s^{-1} cloud has $\sim 10 \text{ km s}^{-1}$ line width, which is the broadest line width of all clouds and also traced by $\text{C}^{18}\text{O } J=1-0$. The RRL velocity coincides with the velocity range of the 94 km s^{-1} cloud. This cloud has the highest peak column density $\sim 10^{23} \text{ cm}^{-2}$ among all clouds, and is connected with the 82 km s^{-1} and 103 km s^{-1} clouds in the velocity space of $^{13}\text{CO } J=1-0$. However, the 115 km s^{-1} cloud is not connected to other clouds. More detailed analysis of these clouds, including the intermediate velocity components, are described in Section 5.4.

4.3.2 $^{13}\text{CO } J=3-2/1-0$ intensity ratios and a comparison to the Spitzer $8 \mu\text{m}$ images

Figures 14 (a), (b), (c), and (d) show the $^{13}\text{CO } J=3-2/1-0$ integrated intensity ratio ($R_{3-2/1-0}^{13}$) maps of the 82 km s^{-1} , 94 km s^{-1} , 103 km s^{-1} , and 115 km s^{-1} cloud, respectively. We mask the region with low $^{13}\text{CO } J=3-2$ intensity ($< 3\sigma$). The intensity ratio of different rotational transition levels is a useful tool to investigate the physical state (gas density and kinematic temperature) of the molecular clouds (e.g., the Large Velocity Gradient model: Goldreich & Kwan 1974). We also present a comparison of $R_{3-2/1-0}^{13}$ for each cloud with the Spitzer $8 \mu\text{m}$ images to clarify the physical association with W43 Main. Figures 14 (e), (f), (g), and (h) show the $^{13}\text{CO } J=3-2$ intensity of the 82 km s^{-1} , 94 km s^{-1} , 103 km s^{-1} , and 115 km s^{-1} clouds by contours superposed on the Spitzer $8 \mu\text{m}$ image, respectively. The ring-like structure traced by the $8 \mu\text{m}$ emission corresponds to the infrared bubble N52 (see Figure 19 of Deharveng et al. 2010).

The 82 km s^{-1} cloud (Figures 14a and 14e) has a high-intensity ratio ($R_{3-2/1-0}^{13} > 0.5$) around the N52 bubble, and corresponds to the brightest part of the $8 \mu\text{m}$ image. The 94 km s^{-1} cloud (Figures 14b and 14f) is distributed over 10 pc around W43 Main, and the intensity ratio ($R_{3-2/1-0}^{13} > 0.5$) is enhanced at the protocluster candidates identified by Motte et al. (2003). In particular, the positions of high-intensity ratio correspond to the W43-MM1 and W43-MM2 ridge identified by Nguyen-Luong et al. (2013). The 103 km s^{-1} cloud (Figures 14c and 14g) has a high-intensity ratio around the bubble, which is a similar trend to the 82 km s^{-1} cloud. The central part of the bubble has a cavity-like structure. The intensity ratio at the W43 MM1 ridge is also enhanced, where the dark cloud is recognized in the $8 \mu\text{m}$ image. The 115 km s^{-1} cloud (Figures 14d and 14h) shows a locally high-intensity ratio near the W43 Main cluster, which corresponds to the bright part of the $8 \mu\text{m}$ image. In addition, clouds at 10 pc away from W43 Main to the north and south also have enhanced intensity ratio ($R_{3-2/1-0}^{13} > 0.8$). The average H_2 density is estimated to be around $6 \times 10^{22} \text{ cm}^{-2} / 20 \text{ pc} \sim 10^3 \text{ cm}^{-3}$ from the ^{13}CO average column density at W43 Main, if we assume that the line of sight extends to 20 pc. The kinetic temperature is found to be $\sim 50 \text{ K}$ with $R_{3-2/1-0}^{13} \sim 0.4$ using the non-LTE code (LADEX⁵: Van der Tak et al. 2007) assuming the input parameters as the line width of 5 km s^{-1} , CO column density of $7.8 \times 10^{16} \text{ cm}^{-2}$ ($= 6 \times 10^{22} / X[^{13}\text{CO}]$), and H_2 density of 10^3 cm^{-3} , respectively. This kinetic temperature is higher than typical for a molecular cloud without star formation. To summarize our results, these four clouds show the effect of heating by ultraviolet radiation from high-mass stars in W43 Main. Therefore, these clouds are likely to be physically associated with W43 Main from the velocity difference of $\sim 10\text{-}20 \text{ km s}^{-1}$.

⁵ <http://var.sron.nl/radex/radex.php>

4.4 G30.5

4.4.1 ^{13}CO and C^{18}O spatial distributions and velocity structures

We find four different velocity clouds at 88 km s^{-1} , 93 km s^{-1} , 103 km s^{-1} , and 113 km s^{-1} for G30.5. Figures 15 (a)-(h) show the integrated intensity maps of ^{13}CO and $\text{C}^{18}\text{O } J=1-0$ emissions of these clouds. The 88 km s^{-1} cloud (Figures 15a and 15e) shows a peaked structure at $(l, b) \sim (30^\circ 39, -0^\circ 10)$, which corresponds to the infrared source of IRAS 18445-0222. The 93 km s^{-1} cloud (Figures 15b and 15f) has a peak of $(l, b) \sim (30^\circ 45, -0^\circ 14)$, and is distributed over 15 pc of the northern side. The 103 km s^{-1} cloud (Figures 15c and 15g) exhibits three CO peaks, which correspond to the infrared sources of G030.404-00.238, IRAS 18447-0229, and G030.213-00.156. The 113 km s^{-1} cloud (Figures 15d and 15h) extends over 20 pc at the direction of the galactic longitude.

We also made a position-velocity diagram to investigate the relationship between these four clouds. Figure 16 shows the Galactic latitude-velocity diagram of (a) ^{13}CO and (b) $\text{C}^{18}\text{O } J=1-0$. The dense gas traced by $\text{C}^{18}\text{O } J=1-0$ demonstrates the four discrete velocity components more clearly. The black boxes present the RRL velocity ($\sim 102.5 \text{ km s}^{-1}$) at $(l, b) \sim (30^\circ 404, -0^\circ 238)$ obtained by Lockman (1989). The RRL lies close to the 103 km s^{-1} clouds. We also present the velocity channel maps in the Appendix Figures 29-31. We observe that G30.5 contains a high amount of molecular gas, while the present star-formation activity appears lower than W43 Main.

4.4.2 $^{13}\text{CO } J=3-2/1-0$ intensity ratios and a comparison to the Spitzer $8 \mu\text{m}$ images

Figures 17 (a)-(d) show $R_{3-2/1-0}^{13}$ maps of the 88 km s^{-1} , 93 km s^{-1} , 103 km s^{-1} , and 113 km s^{-1} clouds, respectively. The clipping levels are adopted at 3σ resulting in 0.8 K km s^{-1} , 1.1 K km s^{-1} , 1.0 K km s^{-1} , and 1.1 K km s^{-1} for the $^{13}\text{CO } J=3-2$ emissions, respectively. Figures 17 (e)-(h) show the $^{13}\text{CO } J=3-2$ (contours) distribution superposed on the Spitzer $8 \mu\text{m}$ images. The 88 km s^{-1} cloud (Figures 17a and 17e) indicates a local high-intensity ratio ($R_{3-2/1-0}^{13} > 0.6$) that corresponds to the infrared source of IRAS 18445-0222 (Figures 17a, 17e). The 93 km s^{-1} cloud (Figures 17b and 17f) has a low ratio ($R_{3-2/1-0}^{13} < 0.3$), but morphological correspondence of the infrared peak at $(l, b) \sim (30^\circ 52, -0^\circ 22)$. The 103 km s^{-1} cloud (Figures 17c, 17g) indicates high $R_{3-2/1-0}^{13} > 0.6$ at G030.213-00.516, G030.404-00.238, IRAS 18447-0229, and G030.489-00.364, which have counter parts in the $8 \mu\text{m}$ image. The 113 km s^{-1} cloud (Figures 17d, 17h) has enhanced $R_{3-2/1-0}^{13} > 0.6$ at the western and eastern side. The $8 \mu\text{m}$ image also corresponds to the high $R_{3-2/1-0}^{13}$ at the eastern side of G30.5. To summarize the results of G30.5, these four clouds are also likely to be partially associated with G30.5 because of high-intensity ratios or morphological correspondence with the infrared images.

4.5 W43 South (G29.96-0.02)

4.5.1 ^{13}CO and C^{18}O spatial distributions and velocity structures

We find two different velocity clouds (93 km s^{-1} and 102 km s^{-1}) for W43 South. Figure 18 shows the integrated intensity maps of ^{13}CO and $\text{C}^{18}\text{O } J=1-0$ emissions, where crosses indicate the radio continuum sources obtained by NVSS (Condon et al. 1998). These sources correspond to the OB-type stars identified by radio continuum observations, where the numbering is the same as in Beltrán et al. (2013). The 93 km s^{-1} cloud (Figures 18a and 18c) has clumpy structures and a peak intensity at the source number 2. This ^{13}CO cloud is distributed over 10 pc in the direction of the Galactic longitude. The 102 km s^{-1} cloud (Figures 18b and 18d) has peak intensities at sources number 4, 5, 8, and 9. These extend from the northern to the southern side. We also demonstrate the velocity channel maps of W43 South in the Appendix Figures 32-34. We made the position-velocity diagram toward W43 South. Figure 19 shows the Galactic longitude-velocity diagram of (a) ^{13}CO , and (b) $\text{C}^{18}\text{O } J=1-0$, respectively. The two clouds can be identified on the position-velocity diagram (Figure 19). The black box shows the RRL velocity (96.7 km s^{-1}) at $(l, b) \sim (29^\circ 944, -0^\circ 042)$ obtained by Lockman et al (1989), which coincides with the intermediate velocity of two clouds. The two clouds converge around $l \sim 29^\circ 9$. We also find a V-shape"-like structure at the center of the RRL velocity (blue dotted lines). From the C^{18}O emission in Figure 19b, the two clouds and V-shape"-like structure can be seen more clearly. We point out that the V-shape exists slightly removed from the overlapping region of the two clouds. We argue that this velocity structure shows a signpost of cloud-cloud collision (e.g., Fukui et al. 2018b). More detailed discussion is described in Section 5.4

4.5.2 $^{13}\text{CO } J=3-2/1-0$ intensity ratios and a comparison to the Spitzer $8 \mu\text{m}$ images

Figures 20(a) and 20(b) show the $R_{3-2/1-0}^{13}$ maps of the 93 km s^{-1} and 102 km s^{-1} clouds, respectively. The clipping levels are adopted at 3σ (0.9 K km s^{-1} , and 1.1 K km s^{-1}) for the $^{13}\text{CO } J=3-2$ emissions. Figures 20 (c) and 20(d) indicate the $^{13}\text{CO } J=3-2$ distributions superposed on the Spitzer $8 \mu\text{m}$ images. The 93 km s^{-1} cloud (Figures 20a and 20c) has high $R_{3-2/1-0}^{13} > 0.6$

around sources number 1, 2, 6, and 7, which correspond to the 8 μm peaks. The 102 km s^{-1} cloud (Figures 20b and 20d) also shows high $R_{3-2/1-0}^{13} > 0.6$ at sources number 1, 5, 8, and 9, which correspond to the 8 μm peaks. These $R_{3-2/1-0}^{13}$ results coincide with the positions of the high dust temperature ($> 70\text{K}$) obtained from the results of Herschel 70-350 μm (see Figure 7 of Beltrán et al. 2013). To summarize the results of W43 South, these two clouds are also likely to be physically associated with W43 South because of their high-intensity ratios and morphological correspondence with the radio continuum sources.

5 Discussion

This section is structured as follows: subsection 5.1 gives a comparison of the brightness temperature with those in other GMCs (W51 and M17); subsection 5.2 shows the star formation efficiency (SFE) of GMCs; subsection 5.3 gives interpretation of the multiple clouds and velocity structures in W43 Main, G30.5, and W43 South; in subsection 5.4 – 5.6 we propose the dense gas and high-mass star formation scenario produced by cloud-cloud collisions in the GMC complex in turbulent conditions. Finally, subsection 5.7 demonstrates the frequency of cloud-cloud collisions in the W43 GMC complex.

5.1 Comparison of the brightness temperature with the W51 and M17 GMCs

We carried out the analysis using histograms of the molecular gas and of the W43, W51, and M17 GMC, aiming to reveal the molecular gas properties of the W43 GMC complex. Figure 21 shows the integrated intensity maps of ^{12}CO , ^{13}CO , and C^{18}O $J=1-0$ for the W51 and M17 GMCs obtained by the FUGIN project.

- The W51 GMC

W51 is a GMC including the high-mass star-forming regions of W51A and W51B (e.g., Carpenter & Sanders 1998; Parsons et al. 2012; Ginsburg et al. 2015, and reference therein). The parallactic distance is estimated to be 5.4 kpc near the tangential direction of the Sagittarius Arm (Sato et al. 2010), which is about the same distance as the W43 GMC complex. The CO gas of three isotopes has a peak intensity at W51A, and the low-density gas traced by ^{12}CO is distributed over 100 pc (Figures 21 a-c). A more detailed analysis of the W51 GMC using the FUGIN data is presented by Fujita et al. (2019b).

- The M17 GMC

M17 is also a GMC, composed of M17 SW and M17 SWex. M17 SW includes the massive cluster NGC 6618 (e.g., Povich et al. 2007; Hoffmeister et al. 2008; Chini & Hoffmeister 2008 and references therein), and M17 SWex has an infrared dark cloud, which is the location of onset of massive star formation (Povich & Whitney 2010). The parallactic distance is derived to be 2.0 kpc, which corresponds to the distance to the Sagittarius Arm (Chibueze et al. 2016). All isotopes of CO have a strong peak at M17 SW, while the diffuse gas is distributed over 30 pc near M17 SWex (Figures 21 d-f). Detailed properties of the M17 cloud using the FUGIN data are described by Yamagishi et al. (2016) and Nishimura et al. (2018).

Figures 22(a), (b), and (c) show the histograms of the brightness temperatures of ^{12}CO , ^{13}CO , and C^{18}O , which correspond to the Brightness Distribution Function (BDF) introduced by Sawada et al. (2012a, 2012b, 2018). We smoothed the data of M17 to $110''$ in order to achieve the same spatial resolution (~ 1 pc) as W43 and W51. We normalized the histograms at (a) 7.3-9.2 K, (b) 5.0-5.8 K, and (c) 1.9-2.1 K. The slope for M17 in ^{12}CO and ^{13}CO (Figures 22a and 22b) is shallower than those for W43 and W51. M17 has excess voxels with high T_{mb} in the BDF. This is consistent with the trend reported by Sawada et al. (2012a, 2012b) that regions containing active star-forming regions show shallower distributions. If the detected emission within the beam is optically thick, the line becomes saturated with T_{mb} , reflecting the gas excitation temperature. Hence the excess with higher T_{mb} than ~ 30 K indicate the extended warm gas component due to H II regions with respect to the cloud extent, as is prominent for M17.

However, the histogram of C^{18}O , which is optically thinner than other isotopes, has a different shape to others, and W43 has a high proportion of dense gas with high brightness temperature (see a black arrow in Figure 22c). This can be interpreted that the dense gas in the W43 GMC has locally a higher column density than the W51 and M17 GMCs.

5.2 Comparison of the star formation efficiency

We estimated the star formation efficiency (SFE) of these GMCs with the aim of clarifying the present star formation activity of the W43 GMC complex. The SFE is given by

$$\text{SFE} = \frac{M_*}{M_* + M_{\text{cloud}}}, \quad (1)$$

where M_{cloud} and M_* are the cloud mass and stellar mass, respectively. We derive the molecular mass from the FUGIN data. A

detailed explanation of our methods is given in Appendix 1. Table 6 shows our results for the SFEs of each GMC complex. The total stellar masses were estimated from the number of earliest O-type star(s) by assuming the number distribution of the Salpeter IMF ($\frac{dN}{dM} \propto M^{-2.35}$; Salpeter 1955). The summation range is adopted from $0.08M_{\odot}$ stars. The earliest spectral types are O3.5III in W43 Main, O5III in W43 South (G29.96-0.02), O4V in W51, and O4V in M17, respectively (see Table 1 in Binder & Povich 2018). The masses of these earliest-type stars are adopted by referring to observational O-star parameters (see Tables 4 and 5 in Martins et al. 2005). The total stellar mass of W43 is derived from summing W43 Main and W43 South, and that of W51 is consistent with the results of infrared spectroscopic observations by Bik et al. (2019).

In Table 6, we see that W43 has a low SFE compared to W51 and M17 calculated using all isotopes. This indicates that W43 has a large proportion of molecular to stellar mass. When we estimate the SFE from the dense gas ($C^{18}O$), W43 shows $\sim 4\%$, which is consistent with other nearby star-forming regions (3% - 6%: Evans et al. 2009), and Orion GMC ($\sim 4\%$: Nishimura et al. 2015). Figure 23 presents the $C^{18}O/^{12}CO$ $J=1-0$ intensity ratio map, which shows the relatively high-density regions in the W43 GMC complex. This map shows high ratios ($\sim 0.07-0.08$) around W43 Main and W43 South, which correspond to the present active star-forming region. Moreover, the W43 GMC complex has locally-high density regions including G30.5. These results indicate that future star formation in W43 is likely to be more active. Therefore, we suggest that while the current SFE of the whole W43 GMC is $\sim 4\%$, the star formation activity in W43 will possibly increase in the future. This possibility is also proposed by Nguyen-Luong et al. (2011) and Motte et al. (2017). We discuss the origin of the dense gas with multiple O-type stars in subsection 5.3 - 5.6, based on the properties of the W43 GMC complex.

5.3 Interpretation of the multiple clouds in W43 Main, G30.5, and W43 South

We find multiple ^{13}CO clouds with a velocity difference of $\sim 10-20$ km s $^{-1}$ for W43 Main, G30.5, and W43 South, which have locally-high column density molecular gas. If we assume a cloud separation of $r = 20-30$ pc and velocity difference of $v = 15$ km s $^{-1} \times \sqrt{2} \sim 20$ km s $^{-1}$, adopting a projection angle of 45° , the total mass required to gravitationally bind can be estimated as

$$M = \frac{rv^2}{2G} \sim 10^6 M_{\odot}. \quad (2)$$

This mass is a factor of two larger than the averaged mass of each ^{13}CO cloud as $5 \times 10^5 M_{\odot}$. We suggest that it is difficult to interpret the ^{13}CO clouds as a gravitationally bound system like the two-body system. Therefore, we hypothesize that the clouds in W43 Main, G30.5, and W43 South collided with each other by chance, and the collisions have produced the dense gas and local mini-starburst in the W43 GMC complex.

5.4 Spectral features indicative of cloud-cloud collisions

When two clouds collide, as a natural consequence of momentum exchange, an intermediate velocity component, so-called the bridge feature is expected to appear between the two clouds (e.g., Haworth et al. 2015a, 2015b). We thus carried out a detailed spectral analysis to investigate the bridge features in W43 Main. Figure 24(a) and (b) illustrate an example ^{13}CO spectrum and an excess emission as a residual of two Gaussian subtraction from the ^{13}CO $J=3-2$ spectrum, respectively. Figure 24(c) shows their spatial distributions of ^{13}CO $J=3-2$, and (d) shows the distribution of the $J=3-2/1-0$ intensity ratio for the bridge component defined as the excess emission. We defined the bridge features by the following procedures using the ^{13}CO data sets of $J=3-2$ and $1-0$ lines.

1. We applied the least-square fittings of the red and blue-shifted components to the Gaussian functions (Figure 24 (a)).
2. We limit the center velocity (V_{cent}) and tried the fittings changing the range of V_{cent} to see the most successful condition. As a result, we set the criteria of subtracting the Gaussian functions if V_{cent} falls in the range of $77 \leq V_{\text{cent}} < 83$ km s $^{-1}$ and $92 \leq V_{\text{cent}} < 100$ km s $^{-1}$ for each component from the original data.
3. The bridge features are thus defined as the residual excess emission with the integrated velocity range from 82.3 to 88.2 km s $^{-1}$ as shown in the green area of figure 24(b).

The bridge features (green contours) are almost exclusively distributed in the region where the two clouds (blue and red contours) overlap in W43 Main. Furthermore, the intensity ratio of the bridge features ($R_{3-2/1-0}^{13} \gtrsim 0.7$) is enhanced from the typical value ($R_{3-2/1-0}^{13} \sim 0.3$) without high-mass star formation in W43. This result shows that the bridge features have high density and/or high temperature around W43 Main.

We also tried to apply the same procedures to W43 South. The spectra are, however, more blended and technically difficult to be decomposed due to relatively large velocity dispersions of the two components, and also to small velocity separation possibly

because of the viewing angle with respect to the relative motion. Hence the bridge features are not identified clearly. The position-velocity diagram better indicate the two velocity components and the bridge feature connecting them (see Figure 19). Higher resolution, higher sensitivity, and more optically thin line data may help the decomposition to reveal more obvious evidence of the collisional interaction in W43 South.

According to the cloud-cloud collision model, the interface layer of two clouds is decelerated and have intermediate velocity, and hence corresponds to the bridge feature that is localized in the overlapping region of two clouds on the plane of the sky. The bridge features are also expected to have high density and/or temperature by the collisional shock compression. Therefore, we suggest that the bridge feature in W43 Main almost originate from cloud-cloud collisions, and support our hypothesis.

5.5 Interpretation of velocity distributions

We also propose that a cloud-cloud collision hypothesis can explain the origin of the V-shape structure on the position velocity diagram (Figure 19). When two clouds having different sizes collide and merge, the cavity is created in the large cloud. If we make the position-velocity diagram toward colliding spots in this stage, we can expect to observe a V-shaped velocity distribution (see Figure 5 middle panel of Haworth et al. 2015a). Indeed, the observations of the isolated compact cluster GM 24 also demonstrated that a cloud-cloud collision can produce the V-shape velocity structure from a comparison to the numerical simulation (see Figure 7 of Fukui et al. 2018b). We note that the V-shape in W43 South exists away from the overlapping region of the 93 km s^{-1} and 102 km s^{-1} clouds. We suggest that this shows another collision occurring to the 102 km s^{-1} cloud. Fujita et al. (2019b) indeed argue that the multiple cloud collisions trigger massive star formation in the W51 GMC.

The stellar feedback might be an alternative interpretation of the complex velocity structures, instead of a cloud-cloud collision. However, we cannot find elliptical velocity distributions on the position-velocity diagram expected for an expanding-shell (e.g., Figure 12 of Fukui et al. 2012). Moreover, the ionization effects in W43 South are likely to be small because of the young high-mass star-forming region ($\sim 0.1 \text{ Myr}$: Watson & Hanson 1997). Indeed, most H II regions in W43 South have a compact size ($< 1 \text{ pc}$: Table 6 of Beltran et al. 2013), and are embedded in the molecular clouds. Dale et al. (2013) reported that the influence of the stellar winds from OB-type stars on molecular clouds is less effective compared to expanding H II regions. Therefore, we conclude that the velocity structures of the clouds in the W43 GMC complex is explained better by the cloud-cloud collision rather than the feedback effect.

5.6 Dense gas and multiple O-type star formation scenario in the W43 GMC complex

Figure 25 (a) shows our proposed model of the top-view schematic images of the W43 GMC complex. The light blue represents the low-density gas traced by ^{12}CO of the Scutum Arm. Our proposed model shows that more small-scale clouds ($\sim 10\text{-}20 \text{ pc}$) collide with each other, and produce the local dense gas. If we roughly assume the colliding cloud size as $20\text{-}30 \text{ pc}$ and the velocity difference of the cloud as $10\text{-}20 \text{ km s}^{-1}$, the collisional time scale is derived as $20\text{-}30 \text{ pc}/(10\text{-}20) \text{ km s}^{-1} \sim 1\text{--}3 \text{ Myr}$. This value is consistent with the age of O-type stars in W43 Main ($1\text{-}6 \text{ Myr}$: Motte et al. 2003; Bally et al. 2010). The stellar age of W43 South is $\sim 0.1 \text{ Myr}$ (Watson & Hanson 1997), which is shorter than the collisional timescale. This might imply that the star formation in the initial phase is triggered by a cloud-cloud collision.

Figure 25(b) presents the Galactic-scale top view of the W43 GMC complex from the North Galactic Pole based on Figure 11 of Sofue et al (2019). The red arrows of Figure 25 show the continuous converging flow along the spiral arm and the long bar in the Milky Way. This mechanism, proposed by previous studies, is a possible theory to explain the origin of cloud-cloud collisions in W43 GMC complex (e.g., Nguyen-Luong et al. 2011, Motte et al. 2014, Renaud et al. 2015). We will describe them in the separate paper since it extends the scope of this paper.

We propose that the cloud-cloud collision scenario in the GMC complex might be able to explain the origin of the CMF being shallower than IMF in W43-MM1 (Motte et al. 2018b). Another super star cluster, NGC 3603, triggered by a cloud-cloud collision (Fukui et al. 2014), was reported to have a top-heavy stellar mass function (Harayama et al. 2008). The Galactic center 50 km s^{-1} cloud is also suggested to have a similar tendency (e.g., Tsuboi et al. 2015; Uehara et al. 2019). This suggestion is also supported by the MHD simulation (Fukui et al. 2019)

5.7 The frequency of cloud-cloud collisions in the W43 GMC complex

We estimated the frequency of cloud-cloud collisions in the W43 GMC complex from the mean free paths, assuming random cloud motion. The collision frequency (τ_{col}) is given by

$$\tau_{\text{col}} = \frac{1}{n_{\text{cl}}\sigma_{\text{cl}}v_{\text{rel}}} \sim 7 \text{ Myr}, \quad (3)$$

where n_{cl} , σ_{cl} , and v_{rel} are the number density, collisional cross-section, and relative velocity. The number of clouds is calculated as the ratio of the ^{13}CO total and average mass as $1.1 \times 10^7 M_{\odot} / 4.6 \times 10^5 M_{\odot} \sim 24$. The number density is derived as $n_{\text{cl}} \sim 2 \times 10^{-5} \text{pc}^{-3}$, assuming a GMC size of $75 \text{ pc} \times 50 \text{ pc} \times 75 \text{ pc}$. The collisional cross-section is estimated as $\sigma_{\text{cl}} = \pi(10 \text{ pc})^2$ assuming a ^{13}CO cloud radius of 10 pc. The relative velocity is adopted as $v_{\text{rel}} = 15 \times \sqrt{2} \sim 20 \text{ km s}^{-1}$ assuming a projection angle of 45° . The results for 7 Myr is factor of 3-4 shorter than the typical age of GMCs, which is 20-30 Myr (e.g., Kawamura et al. 2009). This indicates that ^{13}CO clouds are likely to experience 3-4 collisional events in their life-time, if we assume the random motion of clouds. The Galactic-scale numerical simulation also shows the high merger rate of ~ 2 -3 Myr in the massive GMC like W43 (Fujimoto et al. 2014a).

6 Conclusions

The conclusions of this paper are summarized as follows.

1. We carried out new large-scale CO $J = 1-0$ observations of the W43 GMC complex in the tangential direction of the Scutum Arm as a part of the FUGIN legacy survey. We revealed the spatial distribution of molecular gas and velocity structures.
2. The low-density gas traced by ^{12}CO is distributed in a region of $150 \text{ pc} \times 100 \text{ pc}$ ($l \times b$), and has a large velocity dispersion (20-30 km s^{-1}). The dense gas traced by C^{18}O reveals three high-mass star-forming regions (W43 Main, G30.5, and W43 South), with clumpy structures.
3. We found 2-4 velocity components with velocity difference of ~ 10 -20 km s^{-1} in each region. At least two clouds are likely to be physically associated with high-mass star-forming regions from their common high-intensity ratios of $R_{3-2/1-0}^{13}$ and their similar distribution to infrared nebulae.
4. We made brightness temperature histograms of W43, W51, and M17 GMC, revealing the molecular gas properties of the W43 GMC complex. We showed that localized dense gas has a high brightness temperature compared to the W51 and M17 GMC.
5. The current SFE" of the entire W43 GMC has low value ($\sim 4\%$) compared to the W51 and M17 GMCs. On the other hand, the W43 GMC complex has locally-high density C^{18}O gas from the brightness distribution function. Therefore, we suggest that the star formation activity in W43 will possibly increase in the future.
6. The velocity separation of these clouds in W43 Main, G30.5, and W43 South is too large for each cloud to be gravitationally bound. We also find bridging features and a V-shape structure on the position-velocity diagram. These features are a signpost of cloud-cloud collision, suggested by previous studies. Therefore, we propose that the supersonic cloud-cloud collision hypothesis can explain the origin of dense gas and the local mini-starburst in the W43 GMC complex.
7. We argued that the converging gas flow from the Scutum Arm and the long bar causes the highly turbulent condition, which makes frequent cloud-cloud collisions in the W43 GMC complex.

Appendix 1 Procedures of the physical parameters of the molecular clouds derived from the FUGIN data

In this section, we introduce the calculation method of the physical parameters of the molecular gas, assuming local thermal equilibrium (LTE) (e.g., Wilson et al. 2009; Mangum & Shirley 2015).

- The radiative transfer equation: $[T_{\text{mb}}]$

The observed brightness temperature $[T_{\text{mb}}(v)]$ at radial velocity $[v]$ is given by

$$T_{\text{mb}}(v) = (J(T_{\text{ex}}) - J(T_{\text{bg}}))(1 - \exp(-\tau(v))), \quad (\text{A1})$$

where $J(T)$, T_{ex} , T_{bg} , and $\tau(v)$ are the Rayleigh-Jeans equivalent temperature, the excitation temperature, the background continuum emissions, and the optical depth, respectively. We adopted $T_{\text{bg}} = 2.73$ K, which corresponds to the cosmic microwave background emission.

- The excitation temperature: $[T_{\text{ex}}]$

If we assume that the peak temperature of $^{12}\text{CO } J=1-0$ is optically thick ($\tau \rightarrow \infty$), the excitation temperature is given by

$$T_{\text{ex}} = 5.5 / \ln \left(1 + \frac{5.5}{T_{\text{mb}}(^{12}\text{CO}_{\text{peak}})/\text{K} + 0.82} \right) [\text{K}]. \quad (\text{A2})$$

- The optical depth: $[\tau_{13}(v)]$ and $[\tau_{18}(v)]$

If we assume the same excitation temperatures in ^{12}CO , ^{13}CO , and C^{18}O , the optical depths are derived at each voxel from the ^{13}CO and C^{18}O brightness temperatures, and the excitation temperature by using the following equations:

$$\tau_{13}(v) = -\ln \left[1 - \frac{T_{\text{mb}}(^{13}\text{CO})}{5.3 \text{ K}} \left\{ \frac{1}{\exp(\frac{5.3 \text{ K}}{T_{\text{ex}}}) - 1} - 0.16 \right\}^{-1} \right], \quad (\text{A3})$$

$$\tau_{18}(v) = -\ln \left[1 - \frac{T_{\text{mb}}(\text{C}^{18}\text{O})}{5.3 \text{ K}} \left\{ \frac{1}{\exp(\frac{5.3 \text{ K}}{T_{\text{ex}}}) - 1} - 0.17 \right\}^{-1} \right]. \quad (\text{A4})$$

- The CO column density: $N(^{13}\text{CO})$ and $N(\text{C}^{18}\text{O})$

The ^{13}CO and C^{18}O column densities are calculated by summing all velocity channels from the following equations:

$$N(^{13}\text{CO}) = 2.4 \times 10^{14} \sum_v \frac{T_{\text{ex}} / \text{K} \tau_{13}(v) \Delta v(^{13}\text{CO}) / \text{km s}^{-1}}{1 - \exp(-\frac{5.3 \text{ K}}{T_{\text{ex}}})} [\text{cm}^{-2}], \quad (\text{A5})$$

$$N(\text{C}^{18}\text{O}) = 2.5 \times 10^{14} \sum_v \frac{T_{\text{ex}} / \text{K} \tau_{18}(v) \Delta v(\text{C}^{18}\text{O}) / \text{km s}^{-1}}{1 - \exp(-\frac{5.3 \text{ K}}{T_{\text{ex}}})} [\text{cm}^{-2}], \quad (\text{A6})$$

where $\Delta v(^{13}\text{CO})$ and $\Delta v(\text{C}^{18}\text{O})$ are adopted as velocity channel resolution of 0.65 km s^{-1} .

- The H_2 column density

The H_2 column density is calculated using the following methods, using an X-factor ($X(^{12}\text{CO})$) and abundance ratios of the isotopes.

$$N_{\text{X}}^{12}(\text{H}_2) = X(^{12}\text{CO}) \times W(^{12}\text{CO}) \quad (\text{A7})$$

$$N_{\text{LTE}}^{13}(\text{H}_2) = X[^{13}\text{CO}] \times N(^{13}\text{CO}) \quad (\text{A8})$$

$$N_{\text{LTE}}^{18}(\text{H}_2) = X[\text{C}^{18}\text{O}] \times N(\text{C}^{18}\text{O}) \quad (\text{A9})$$

We adopted an X-factor of $2.0 \times 10^{20} [(\text{K kms}^{-1})^{-1} \text{ cm}^{-2}]$ with having a $\pm 30\%$ uncertainty (Bolatto et al. 2012). When we converted to the H_2 column densities from the ^{13}CO and C^{18}O emission, we utilized the conversion factor of $X[^{13}\text{CO}] = 7.7 \times 10^5$ and $X[\text{C}^{18}\text{O}] = 5.6 \times 10^6$. These factors are derived from the isotope abundance ratio of $[^{12}\text{C}]/[^{13}\text{C}] = 77$, $[^{16}\text{O}]/[^{18}\text{O}] = 560$ (Wilson & Rood 1994), and the CO and H_2 abundance ratio of $[^{12}\text{CO}]/[\text{H}_2] = 10^{-4}$ (e.g., Frerking et al. 1982; Pineda et al. 2010).

- Total molecular mass

The total molecular mass is given by

⁶ <http://montage.ipac.caltech.edu>

$$M = \mu_{\text{H}_2} m_{\text{H}} D^2 \sum_i \Omega N_i(\text{H}_2), \quad (\text{A10})$$

where $\mu_{\text{H}_2} \sim 2.8$ is mean molecular weight per hydrogen molecule including the contribution of helium (e.g., Appendix A.1. of Kauffmann et al. 2008), $m_{\text{H}} = 1.67 \times 10^{-24}$ g is the proton mass, D is the distance to each GMC, and Ω is the solid angle of pixel i .

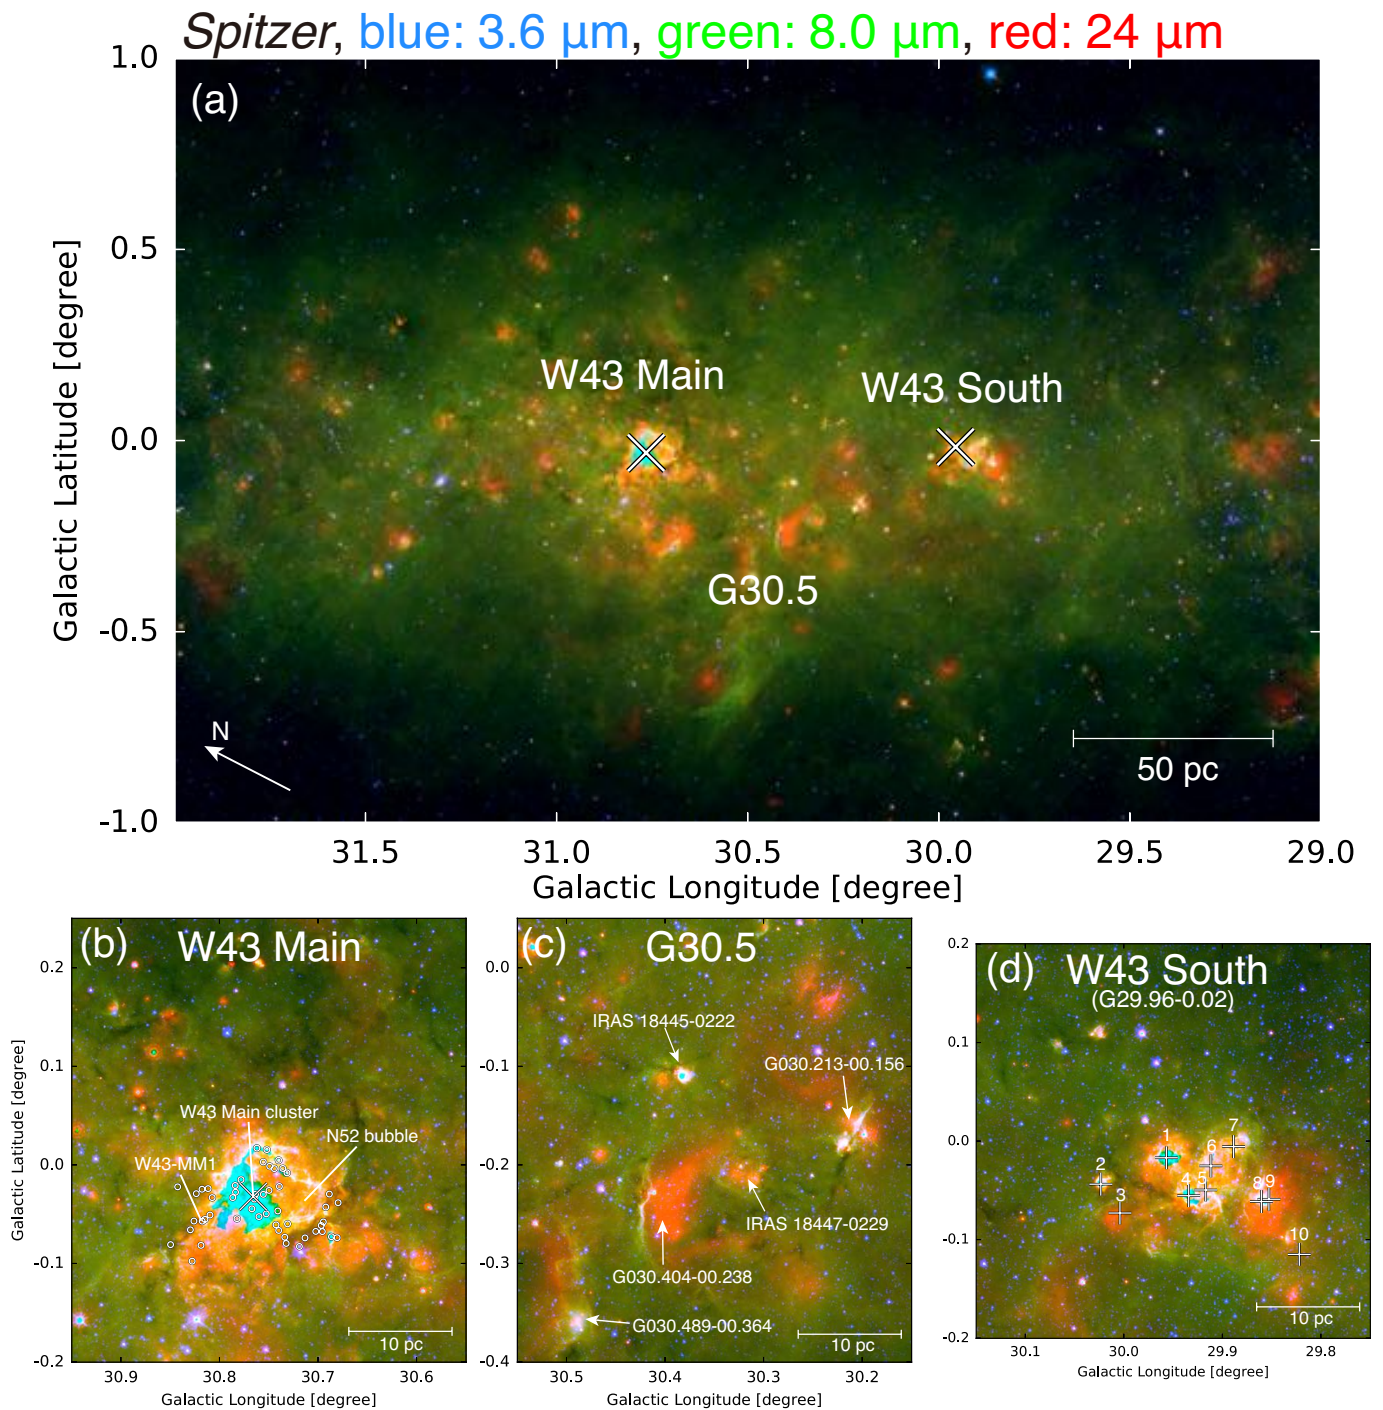

Fig. 1. (a) Spitzer three-color composite image of W43. Blue, green, and red represent the Spitzer/IRAC 3.6 μm , Spitzer/IRAC 8 μm (Benjamin et al. 2003), and Spitzer/MIPS 24 μm (Carey et al. 2009) distributions. The X marks indicate W43 Main (Blum et al. 1999) and W43 South (Wood & Churchwell 1989). (b) Close-up image of W43 Main. The white circles indicate the 51 protocluster candidates (W43 MM1-MM51) cataloged by Motte et al. (2003). (c) Close-up image of G30.5. (d) Close-up image of W43 South. The white crosses indicate the radio continuum sources identified by Condon et al. (1998).

Table 1. Properties of W43 Main and W43 South.

| Name | Total luminosity | # of O-type stars | Age | References |
|-----------|------------------------------|-------------------|----------------|-------------|
| W43 Main | $7-10 \times 10^6 L_{\odot}$ | $\sim 14 - 50$ | 1–6 Myr | [1,2,3,4,5] |
| W43 South | $2-6 \times 10^6 L_{\odot}$ | 6 | ~ 0.1 Myr | [2,6,7] |

Table 2. Spectral types of O-type stars in the W43 Main cluster.

| Name | Galactic Longitude | Galactic Latitude | Spectral Type |
|---------|--------------------|--------------------|---------------|
| W43 #1a | $30^{\circ}766995$ | $-0^{\circ}034752$ | WN7 |
| W43 #1b | $30^{\circ}766884$ | $-0^{\circ}034631$ | O4 III |
| W43 #2 | — | — | O3.5 III |
| W43 #3a | $30^{\circ}766215$ | $-0^{\circ}035086$ | O3.5 V/O4 V |
| W43 #3b | $30^{\circ}766167$ | $-0^{\circ}034975$ | O3.5 V/O4 V |

Table 3. Spectral types of OB-type stars in W43 South.

| Number | Galactic Longitude | Galactic Latitude | Spectral Type |
|--------|--------------------|-------------------|---------------|
| #1 | $29^{\circ}957$ | $-0^{\circ}0170$ | O6 |
| #2 | $30^{\circ}023$ | $-0^{\circ}0438$ | B0 |
| #3 | $30^{\circ}004$ | $-0^{\circ}0730$ | B0 |
| #4 | $29^{\circ}934$ | $-0^{\circ}0555$ | O5 |
| #5 | $29^{\circ}917$ | $-0^{\circ}0497$ | O6.5 |
| #6 | $29^{\circ}912$ | $-0^{\circ}0252$ | O9.5 |
| #7 | $29^{\circ}889$ | $-0^{\circ}0056$ | O8.5 |
| #8 | $29^{\circ}860$ | $-0^{\circ}0614$ | O9.5 |
| #9 | $29^{\circ}853$ | $-0^{\circ}0591$ | B0 |
| #10 | $29^{\circ}822$ | $-0^{\circ}1150$ | B0.5 |

The clipping level is adopted as 5σ (~ 5 K of ^{12}CO and 1.75 K of ^{13}CO , C^{18}O , $J=1-0$). The integrated velocity range of the total molecular gas is 78 to 120 km s⁻¹.

The velocity clouds of W43 Main, G30.5, and W43 South are the same as in Figures 12, 15, and 18, respectively.

Columns: (1) Name. (2) Peak H₂ column density from ^{12}CO assuming the X-factor. (3) Average H₂ column density of the cloud from ^{12}CO assuming the X-factor. (4) Peak H₂ column density from ^{13}CO assuming the LTE. (5) Average H₂ column density of the cloud from ^{13}CO assuming the LTE. (6) Peak H₂ column density from C^{18}O assuming the LTE. (7) Average H₂ column density of the cloud from C^{18}O assuming the LTE. (8) Total H₂ mass from ^{12}CO assuming the X-factor. (9) Total H₂ mass from ^{13}CO assuming the LTE. (10) Total H₂ mass from C^{18}O assuming the LTE.

Fig. 11. Spectra for ^{12}CO , ^{13}CO , and C^{18}O $J=1-0$ obtained at (a) W43 Main, (b) G30.5, and (c) W43 South. The red arrows indicate the velocity components associated with the W43 GMC complex. The position of each spectrum shows the upper right of each panel.

Fig. 12. (a), (b), (c), (d) Integrated intensity map of $^{13}\text{CO } J=1-0$ for the (a) 82 km s^{-1} , (b) 94 km s^{-1} , (c) 103 km s^{-1} , and (d) 115 km s^{-1} cloud. The Xs indicate the W43 Main cluster (Blum et al. 1999). The white circles present the 51 protocluster candidates (W43 MM1-MM51) cataloged by Motte et al. (2003). The final beam size after convolution is $\sim 40''$. (e), (f), (g), (h) Integrated intensity map of $\text{C}^{18}\text{O } J=1-0$ obtained for the (e) 82 km s^{-1} , (f) 94 km s^{-1} , (g) 103 km s^{-1} , and (h) 115 km s^{-1} cloud.

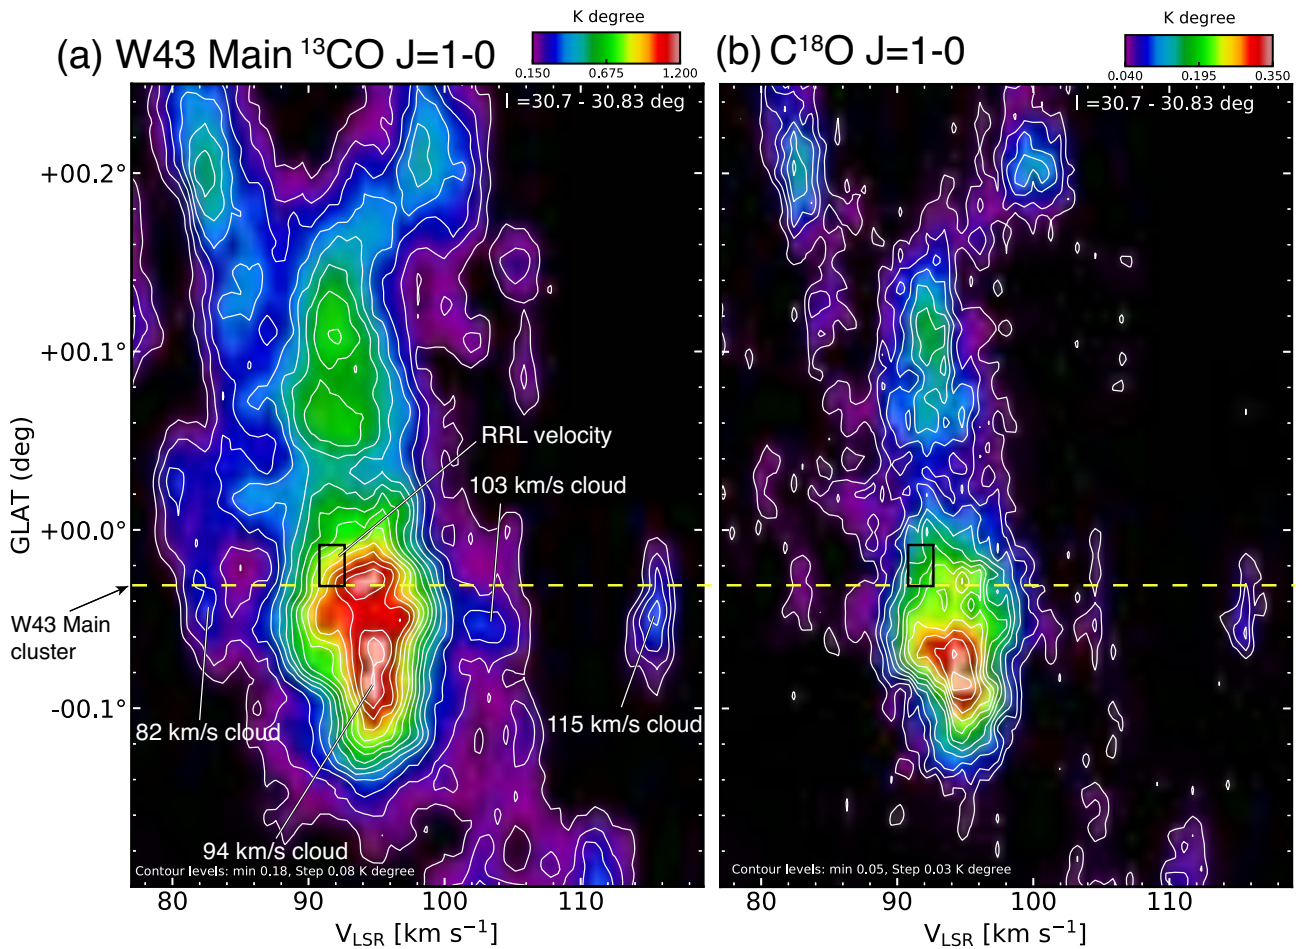

Fig. 13. Galactic latitude-velocity diagram of (a) ^{13}CO and (b) $\text{C}^{18}\text{O } J = 1-0$ integrated over the latitude range from 30.7° to 30.83° . The contour levels and intervals are 0.18 K degree and 0.08 K degree of (a), 0.05 K degree and 0.03 K degree of (b), respectively. The black boxes show the radio recombination line velocity (91.7 km s^{-1}) at $(l, b) = (30.780, -0.020)$ from Luisi et al (2017), where their resolution is $\sim 1.86 \text{ km s}^{-1} \times 82''$. The yellow dashed line indicates the position of the W43 Main cluster (Blum et al. 1999).

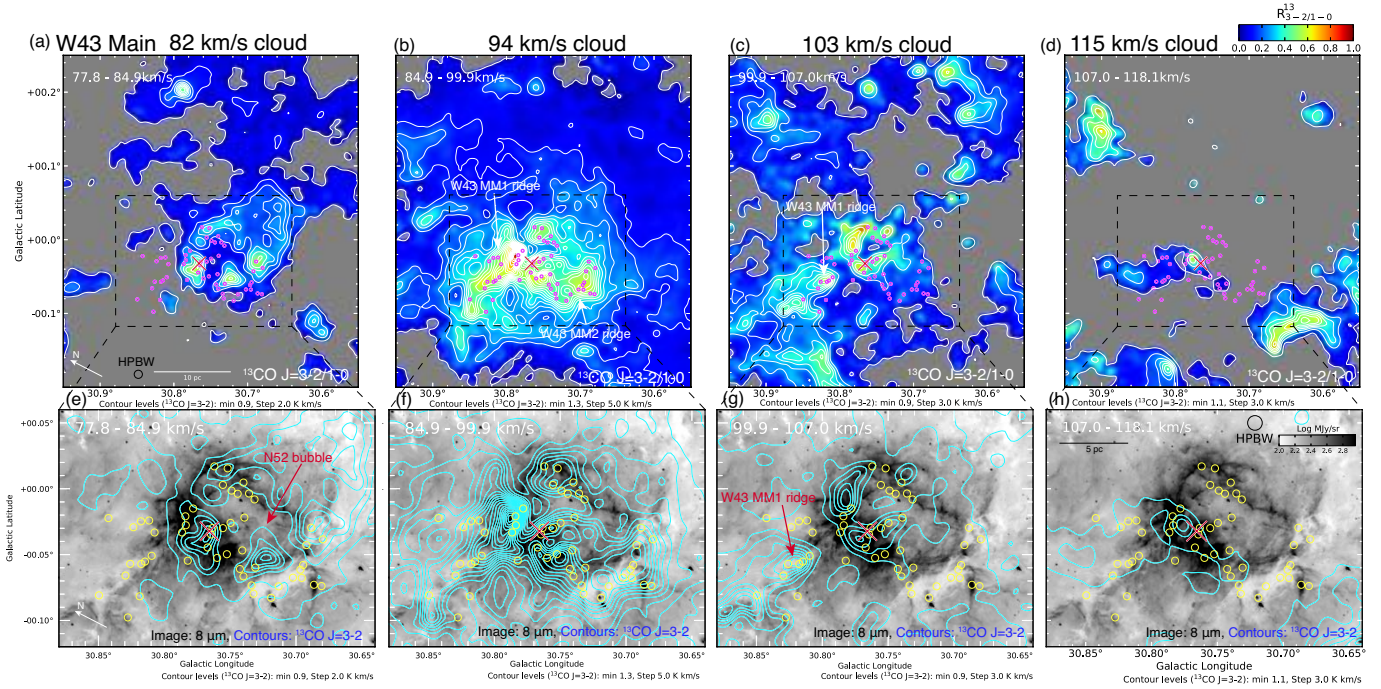

Fig. 14. (a), (b), (c), (d) Intensity ratio map of $^{13}\text{CO } J = 3-2 / ^{13}\text{CO } J = 1-0$ from JCMT and FUGIN for the (a) 82 km s^{-1} , (b) 94 km s^{-1} , (c) 103 km s^{-1} , and (d) 115 km s^{-1} cloud. The Xs indicate W43 Main cluster (Blum et al. 1999). The circles indicate the 51 compact fragments (W43 MM1-MM51) cataloged by Motte et al. (2003). The final beam size after convolution is $\sim 40''$. The clipping levels are adopted as 3σ ($\sim 0.9 \text{ K km s}^{-1} \sim 1.3 \text{ K km s}^{-1}$, $\sim 0.9 \text{ K km s}^{-1}$, and $\sim 1.1 \text{ K km s}^{-1}$) of each integrated velocity range. (e), (f), (g), (h) Integrated intensity map of $^{13}\text{CO } J = 3-2$ (contours) obtained with JCMT (CHIMPS) superposed on the Spitzer $8 \mu\text{m}$ image for the (e) 82 km s^{-1} , (f) 94 km s^{-1} , (g) 103 km s^{-1} , and (h) 115 km s^{-1} cloud.

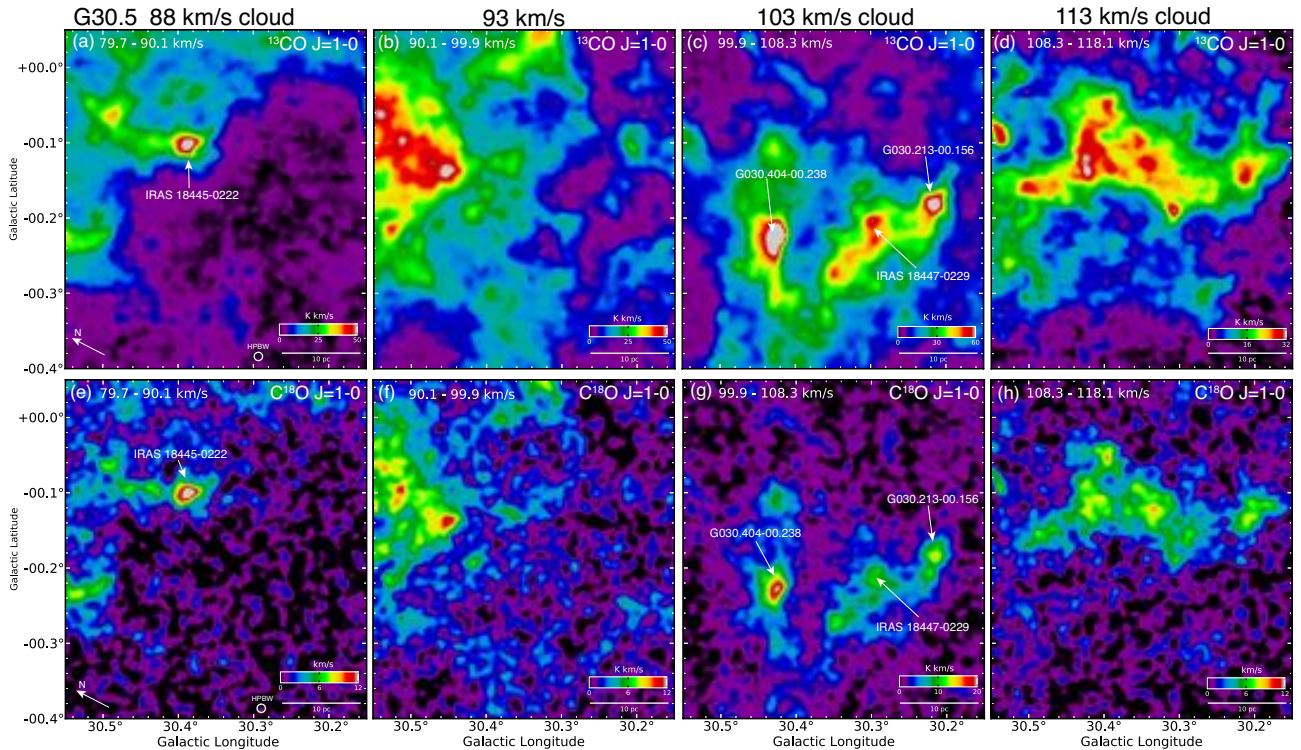

Fig. 15. (a), (b), (c), (d) Integrated intensity map of $^{13}\text{CO } J = 1-0$ for the (a) 88 km s^{-1} , (b) 93 km s^{-1} , (c) 103 km s^{-1} and (d) 113 km s^{-1} . The final beam size after convolution is $\sim 40''$. (e), (f), (g), (h) Integrated intensity map of $\text{C}^{18}\text{O } J = 1-0$ for the (e) 88 km s^{-1} , (f) 93 km s^{-1} , (g) 103 km s^{-1} and (h) 113 km s^{-1} cloud.

Fig. 16. Galactic latitude-velocity diagram of (a) ^{13}CO and (b) C^{18}O $J=1-0$ integrated over the latitude range from $30^\circ 15$ to $30^\circ 55$. The black boxes show the radio recombination line velocity ($\sim 102.5 \text{ km s}^{-1}$) at $(l, b) \sim (30^\circ 404, -0^\circ 238)$ from Lockman (1989), where their resolution is $\sim 4 \text{ km s}^{-1} \times 3'$. The contour levels and intervals are 0.25 K degree and 0.15 K degree of (a), 0.12 K degree and 0.05 K degree of (b), respectively

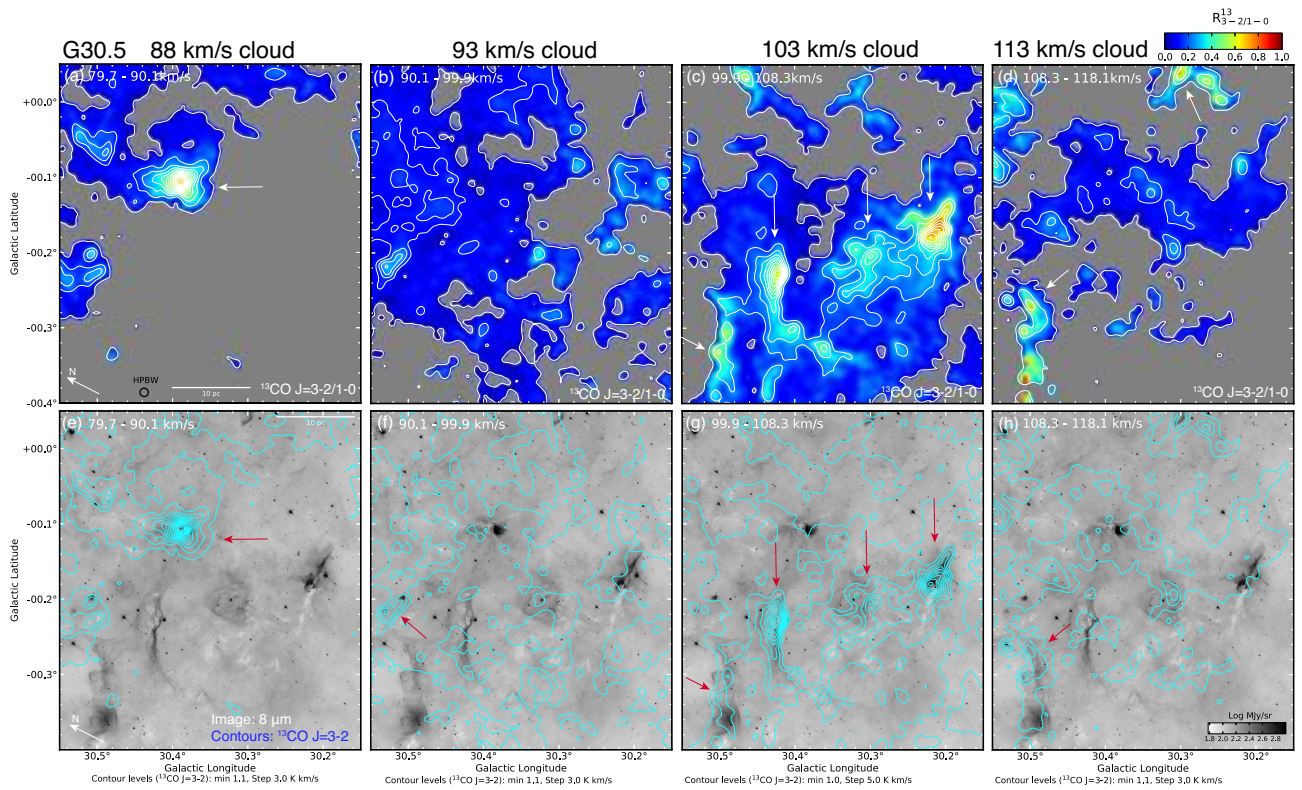

Fig. 17. (a), (b), (c), (d) Intensity ratio map of $^{13}\text{CO } J=3-2/^{13}\text{CO } J=1-0$ from JCMT and FUGIN for the (a) 88 km s^{-1} cloud, (b) 93 km s^{-1} cloud, (c) 103 km s^{-1} cloud and (d) 113 km s^{-1} cloud. The final beam size after convolution is $\sim 40''$. The clipping levels are adopted as 3σ ($\sim 0.8 \text{ K km s}^{-1}$, $\sim 1.1 \text{ K km s}^{-1}$, $\sim 1.0 \text{ K km s}^{-1}$, and $\sim 1.1 \text{ K km s}^{-1}$) of each integrated velocity range. (e), (f), (g), (h) Integrated intensity map of $^{13}\text{CO } J=3-2$ (contours) obtained by JCMT superposed on the Spitzer 8 μm image for the (e) 88 km s^{-1} cloud, (f) 93 km s^{-1} cloud, (g) 103 km s^{-1} cloud and (h) 113 km s^{-1} cloud.

Fig. 18. (a), (b) Integrated intensity map of $^{13}\text{CO } J = 1-0$ for the (a) 93 km s^{-1} cloud and (b) the 102 km s^{-1} cloud. The crosses indicate radio continuum sources identified by the NVSS survey (Condon et al. 1998), and the numbering is the same as in Beltrán et al. (2013). The final beam size after convolution is $\sim 40''$. (c), (d) Integrated intensity map of $\text{C}^{18}\text{O } J = 1-0$ for (c) the 93 km s^{-1} cloud and (d) the 102 km s^{-1} cloud.

Fig. 19. Galactic longitude-velocity diagram of (a) ^{13}CO and (b) $\text{C}^{18}\text{O } J=1-0$ integrated over the latitude range from $-0^\circ 15$ to $0^\circ 05$. The contour levels and intervals are 0.3 K degree and 0.1 K degree of (a), 0.08 K degree and 0.04 K degree of (b), respectively. The black boxes show the H110 α radio recombination line velocity ($\sim 96.7 \text{ km s}^{-1}$) at $(l, b) \sim (29^\circ 944, -0^\circ 042)$ from Lockman (1989), where their resolution is $\sim 4 \text{ km s}^{-1} \times 3'$. The blue dotted lines present the V-shape like structure.

Fig. 20. (a), (b) Intensity ratio map of $^{13}\text{CO } J=3-2/^{13}\text{CO } J=1-0$ from JCMT and FUGIN for the (a) 93 km s^{-1} cloud and (b) 102 km s^{-1} cloud. The crosses indicate radio continuum sources identified by the NVSS survey (Condon et al. 1998), and the numbering is the same as in Beltrán et al. (2003). The final beam size after convolution is $\sim 40''$. The clipping levels are adopted as 3σ ($\sim 0.9 \text{ K km s}^{-1}$ and $\sim 1.1 \text{ K km s}^{-1}$) of each integrated velocity range. (c), (d) Integrated intensity map of $^{13}\text{CO } J=3-2$ (contours) obtained with JCMT superposed on the Spitzer 8 μm image for the (c) 93 km s^{-1} cloud and (d) 102 km s^{-1} cloud.

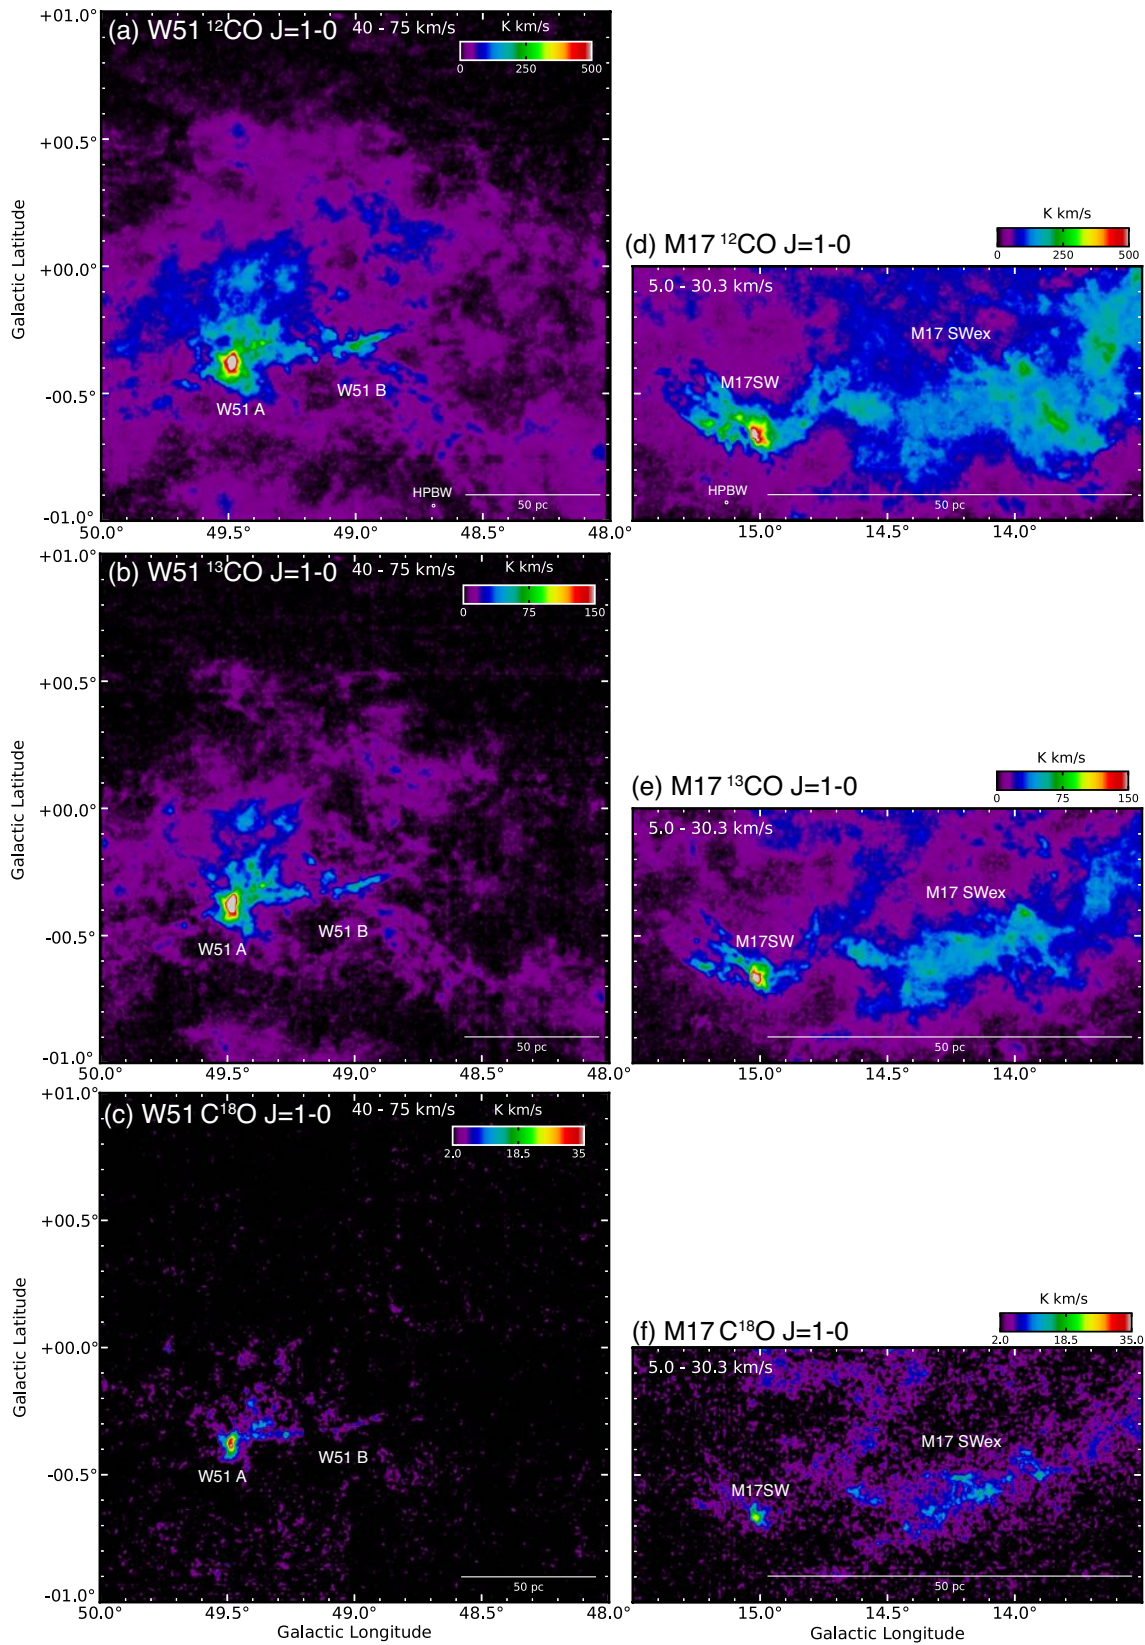

Fig. 21. Integrated intensity maps of (a,d) ^{12}CO , (b,e) ^{13}CO , and (c,f) C^{18}O $J=1-0$ for the W51 and M17 GMC obtained with FUGIN. The integrated velocity range of W51 and M17 is from 40 km s^{-1} to 75 km s^{-1} and from 5 km s^{-1} to 30 km s^{-1} , respectively.

Table 6. Physical properties and Star Formation Efficiency (SFE) of W43, W51, and M17

| Name | M_x^{12} [M_\odot] | M_{LTE}^{13} [M_\odot] | M_{LTE}^{18} [M_\odot] | Stellar mass [M_\odot] | SFE $_{12\text{CO}}$ [%] | SFE $_{13\text{CO}}$ [%] | SFE $_{\text{C}^{18}\text{O}}$ [%] |
|---------|-----------------------------|--|--|-------------------------------|-----------------------------|-----------------------------|---------------------------------------|
| (1) | (2) | (3) | (4) | (5) | (6) | (7) | (8) |

\dagger The total stellar mass of W43 is calculated by summing up W43 Main and W43 South (G29.96-0.02).

Columns: (1) Name. (2) Total H_2 mass from ^{12}CO assuming the X-factor. (3) Total H_2 mass from ^{13}CO assuming the LTE. (4) Total H_2 mass from C^{18}O assuming the LTE. (5) The total stellar mass derived by assuming the IMF from the earliest spectral type star(s) referring to Binder & Povich (2018). The masses of O-type star(s) are adopted from the observational stellar parameters of Tables 4 and 5 in Martins et al. (2005). (6) Star formation efficiency derived by the total H_2 mass from ^{12}CO . (7) Star formation efficiency derived by the total H_2 mass from ^{13}CO . (8) Star formation efficiency derived by the total H_2 mass from C^{18}O .

Fig. 22. Histogram of the brightness temperature of the voxels in the W43, W51, and M17 GMC from (a) ^{12}CO , (b) ^{13}CO , and (c) C^{18}O $J=1-0$, respectively. The frequency is normalized by 7.3-9.2 K, 5.0-5.8 K, and 1.9-2.1 K, respectively. The clipping levels are adopted as 5σ of each region.

Fig. 23. Intensity ratio map of $C^{18}O/^{12}CO$ $J = 1-0$ for the W43 GMC complex. The white crosses indicate W43 Main (Blum et al. 1999) and W43 South (Wood & Churchwell 1989). The clipping levels are adopted as 5σ .

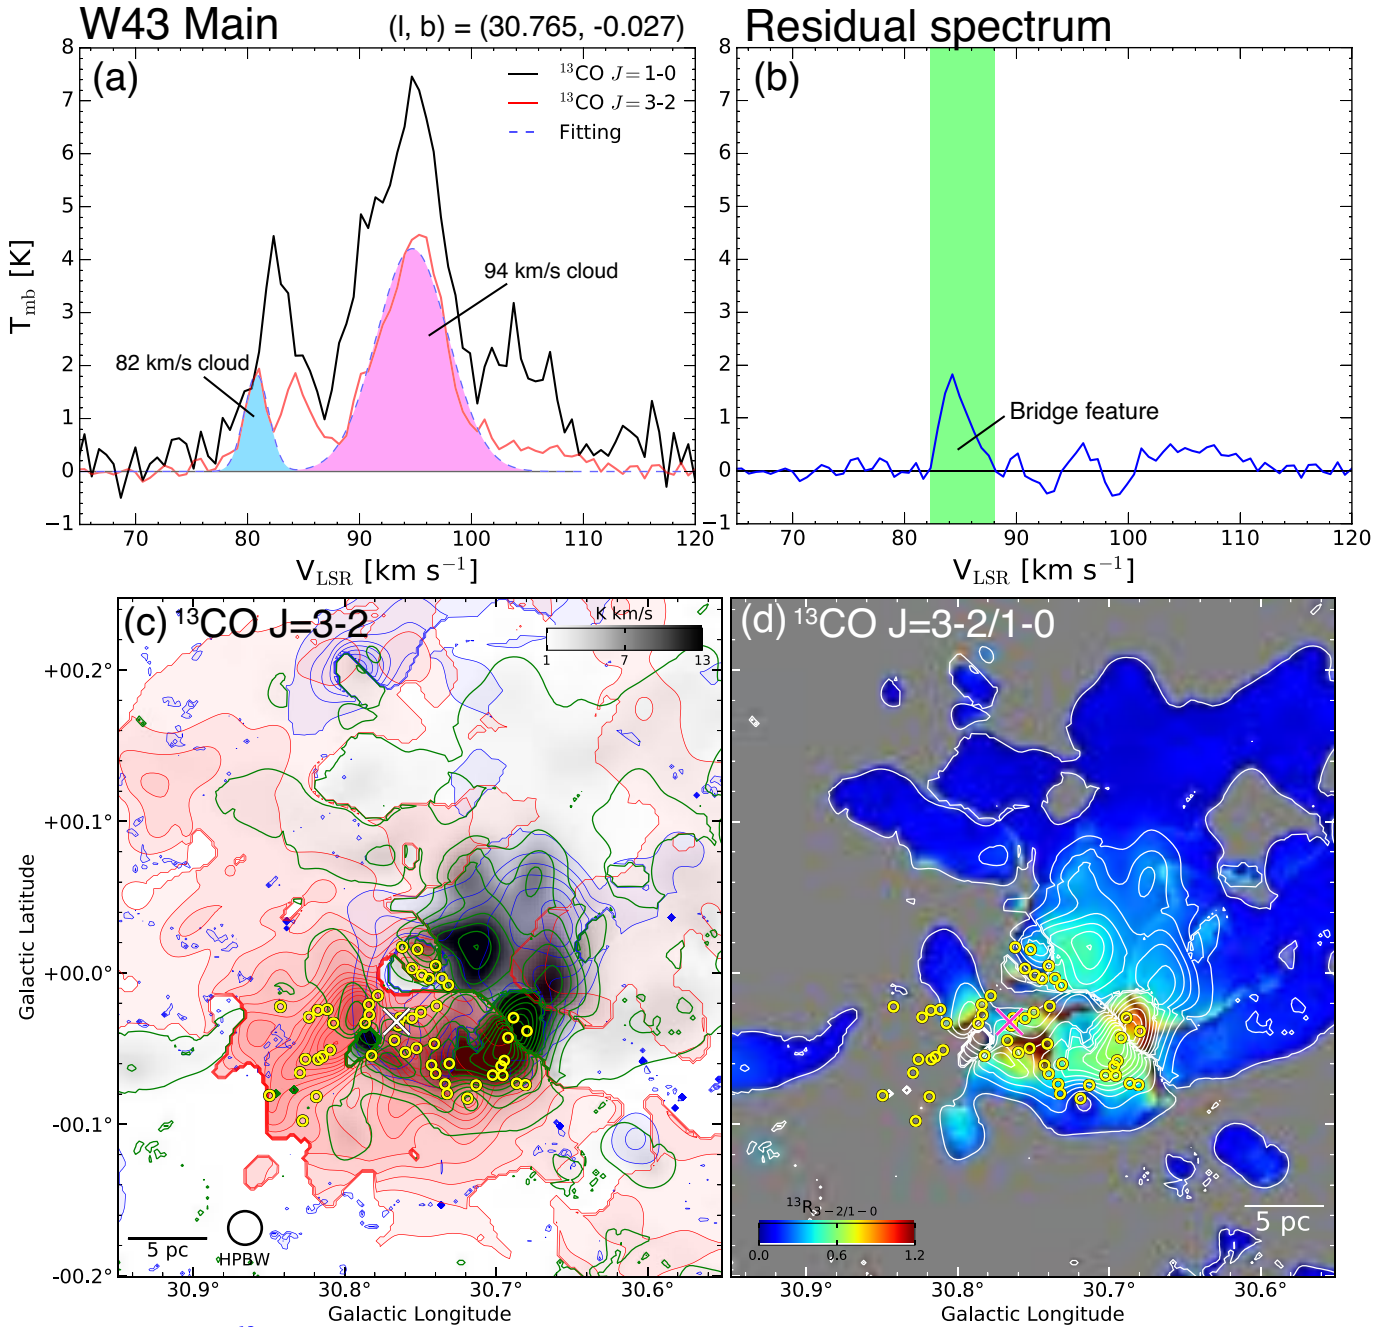

Fig. 24. (a) The spectra and the Gaussian fitting results of the $^{13}\text{CO } J=3-2$ emission in W43 Main. (b) The residual spectrum of $^{13}\text{CO } J=3-2$. The green area indicates the integrated velocity range of the bridge feature. (c) The spatial distributions of bridges (green contours) superposed on the two clouds (blue and red contours) in W43 Main. (d) The $R_{3-2/1-0}$ map of bridges in W43 Main. The clipping level is adopted as 1.5 K km s^{-1} . The data was smoothed to be a spatial resolution of $\sim 80''$. Plots and symbols are the same as Figure 1 (b).

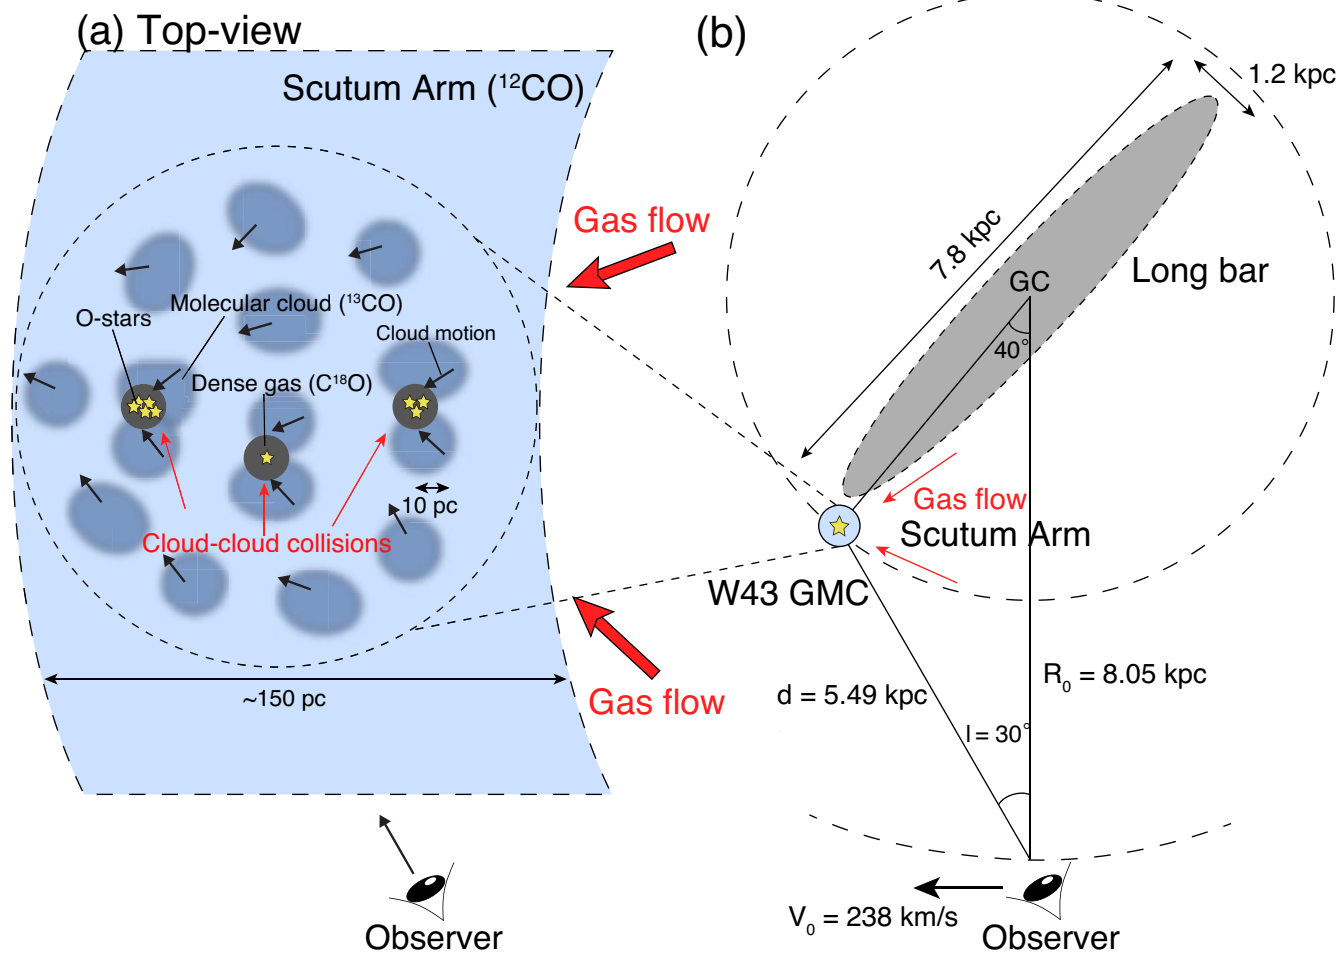

Fig. 25. Schematic picture of our proposed dense gas and O-type star formation scenario of the W43 GMC complex in (a) ~ 100 pc scale and (b) the Galactic-scale. The Galactic-scale illustration is based on Figure 11 of Sofue et al (2019). The distance to the Galactic center (R_0) and W43 (d) are adopted from the VLBI astrometry results obtained by Honma et al. (2012) and Zhang et al. (2014), respectively. The solar constant (V_0) is adopted from Honma et al. (2012). The long-bar parameters are adopted as 7.8 kpc of the major axis, 1.2 kpc of the minor axis, and 43° of the position angle from the Galactic center-Sun axis based on López-Corredoira et al. (2007).

2 CO velocity channel maps of W43 Main, G30.5, and W43 South with FUGIN

We show the velocity channel maps of the ^{12}CO , ^{13}CO , C^{18}O $J = 1-0$ emissions toward W43 Main, G30.5, and W43 South, respectively. The velocity range is between 66.1 and 124.6 km s^{-1} .

Fig. 26. Velocity channel map of the $^{12}\text{CO } J = 1-0$ emission focused on W43 Main with a velocity step of 3.9 km s^{-1} . The white crosses indicate the W43 Main cluster (Blum et al. 1999). The white circles present the 51 compact fragments (W43 MM1-MM51) cataloged by Motte et al. (2003). The final beam size after convolution is $40''$.

Fig. 27. Same as Figure 26, but for $^{13}\text{CO } J=1-0$.

Fig. 28. Same as Figure 26, but for C¹⁸O J=1-0.

Fig. 29. Velocity channel map of the $^{12}\text{CO } J = 1-0$ emission focused on G30.5 with a velocity step of 3.9 km s^{-1} . The final beam sizes after convolution is $40''$.

Fig. 30. Same as Figure 29, but for $^{13}\text{CO } J=1-0$.

Fig. 31. Same as Figure 29, but for C¹⁸O $J = 1-0$.

Fig. 32. Velocity channel map of the $^{12}\text{CO } J = 1-0$ emission focused on W43 South with a velocity step of 3.9 km s^{-1} . The crosses indicate the radio continuum sources identified by the NVSS survey (Condon et al. 1998). The final beam size after convolution is $40''$.
