Abstract

A 10-GHz radio continuum survey of the galactic plane in the range $355^\circ \leq l \leq 56^\circ$, $-1.5 \leq b \leq +1.5$ was made at the Nobeyama Radio Observatory using the 45-m telescope. The half-power beam size of the resultant map is 3'.0 and the noise level of the resultant map is typically 15 mK in brightness temperature. Thirty-one contour maps and a list of 144 small-diameter sources are presented.

Key words: Galactic structure; Radio continuum survey; Radio sources; The Galaxy.

1. Introduction

The radio continuum emission from the Galaxy is mainly composed of the synchrotron emission radiated by the interaction between relativistic electrons and the galactic magnetic field, and of the thermal emission by free-free transitions in ionized (H II) gases. These two types of emission can be separated by their spectra. At higher frequency the synchrotron emission from the galactic plane becomes weak, and we can easily recognize the weak and/or distant H II regions, Crablike supernova remnants, inverted spectrum sources, and diffuse thermal emission. The turnover frequency of the galactic background emission from nonthermal to thermal is about 3 GHz, and at 15.5 GHz about 70% to 90% of the radiation is of thermal origin (Hirabayashi 1974).

A number of continuum surveys have been made so far at various frequencies to investigate the galactic diffuse emission and discrete sources [for example, Altenhoff et al. (1970) at 1.4, 2.7, and 5 GHz, Day et al. (1972) at 2.7 GHz, Reich et al. (1984) at 2.7 GHz, Altenhoff et al. (1979) at 4.9 GHz, Haynes et al. (1978) at 5 GHz]. Among them the Effelsberg 4.875-GHz survey (Altenhoff et al. 1979) was made at the highest frequency with the sharpest beam (2'.6). However, it is difficult to separate

[†] Nobeyama Radio Observatory, a branch of the Tokyo Astronomical Observatory, University of Tokyo, is a facility open for general use by researchers in the field of astronomy, astrophysics, and astrochemistry.

thermal and nonthermal components using previous surveys.

To investigate the galactic thermal emission and flat/inverted spectrum objects, we conducted a survey of the galactic plane at 10 GHz using the 45-m telescope at the Nobeyama Radio Observatory (NRO). A part of this survey ($21^\circ \leq l \leq 26^\circ$, $-1^\circ \leq b \leq +1^\circ$) has been already published (Sofue et al. 1984), in which a Crablike supernova remnant, two H II rings, and weak nonthermal sources were found.

This paper presents the main part of the survey work covering the narrow galactic ridge region of $356^\circ \leq l \leq 56^\circ$, $-1.5 \leq b \leq +1.5$.

2. Observations

The observations were made in March, April, and June 1983, in May, June, August, September, and December 1984, in June 1985, and in June 1986. It took 26 fine weather days to complete the observations and the total observing time with useful data was about 105 hr. The center frequency was 10.05 GHz in March and April 1983, and 10.55 GHz in June 1983 to September 1984. The instantaneous bandwidth was 500 MHz in both periods. Since September 1984, a multichannel backend, which can acquire radio continuum data at some different frequencies simultaneously, was available. We used a two-channel mode with center frequencies of 10.05 and 10.55 GHz. The instantaneous bandwidth was 500 MHz for either channel. As a result, almost the whole area of the survey was observed at 10.55 GHz except the

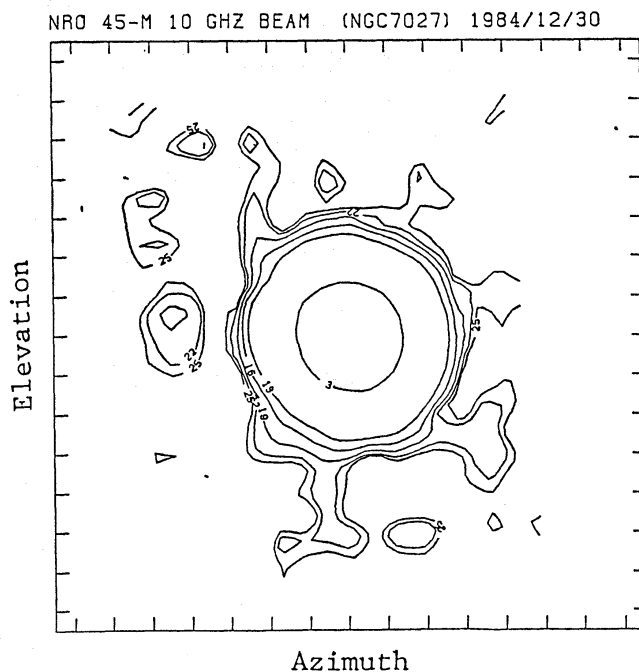

Fig. 1. Antenna beam pattern (point response pattern) at 10 GHz of the NRO 45-m telescope. Horizontal and vertical directions correspond to azimuthal and elevational directions, respectively. The pattern could be well approximated by a Gaussian pattern. The side-lobe level was less than -16 dB of the peak intensity. The contour levels are -3 , -13 , -16 , -19 , -22 , and -25 dB with respect to the peak intensity. The tick marks along the frame of the map are separated by $1'$.

Table 1. Observational parameters.

a. Data acquisition system.

Receiver	Cooled parametric amplifier combined with a Dicke-switch
Backend: until August 1983	1-channel digital detector
since September 1983	2-channel multiplex digital detector
T_{sys}	200 K
HPBW of the antenna	2'.66
T_{B}/S	0.453 K in T_{B}/Jy (for 2'.66 beam)
Bandwidth	500 MHz

b. Center frequencies.

Observing period	Center frequency
March 1983–June 1983	10.05 GHz
September 1983–September 1984	10.55 GHz
September 1984–June 1986	10.05 GHz, 10.55 GHz

c. Flux Density Calibrators.

Observing period	Calibrator	Flux density
1984–1986	NGC 7027	6.61 Jy at 10.55 GHz 6.65 Jy at 10.05 GHz
March–June 1983	3C 348	4.10 Jy at 10.05 GHz*
June 1983	3C 48	2.82 Jy at 10.05 GHz
April 1983	3C 123	7.94 Jy at 10.55 GHz

* Peak flux density with 2'.66 beam.

$l \leq 358^\circ$ region, which was observed only at 10.05 GHz. About 40% of the whole area was observed at both frequencies. We combined all the data to make a final survey map.

The half-power beamwidth of the 45-m telescope was 2'.66 at 10 GHz. The antenna beam pattern was well fitted by a Gaussian pattern and the side-lobe level was less than -16 dB of the peak intensity. The conversion factor from main beam flux density to main beam brightness temperature T_{B} is $0.453 \text{ K} = 1 \text{ Jy}$. Figure 1 shows the antenna response pattern to a point source, which was obtained from a map of NGC 7027.

The final map was made by joining many maps each of which was obtained at one observational sequence of scans. (Hereafter we refer to the small maps as element maps.) The typical size of an element map is $\Delta l \times \Delta b = 3^\circ \times 2^\circ$. Each element map was acquired by raster scans of 60° inclination from the north (in the equatorial coordinates) toward the west (position angle = -60°), in order to scan almost perpendicularly to the galactic plane. The length of each scan was 3'.0 or 3'.2. Only for $-2^\circ 0' \leq l \leq +2^\circ 0'$ and some areas where strong sources exist near $b = +1^\circ 5'$ or $-1^\circ 5'$, the scan length was 4'.0. Several element maps were obtained by taking 2'.0 or 2'.14 scans. Each scan took 50 s and the scan separation was 0'.02. About a half of the survey area was observed more than twice. The rms noise in the resultant map was 30–140 mJy/beam or 14–63 mK in T_{B} depending mainly on weather conditions. Table 1 lists observational parameters of the survey.

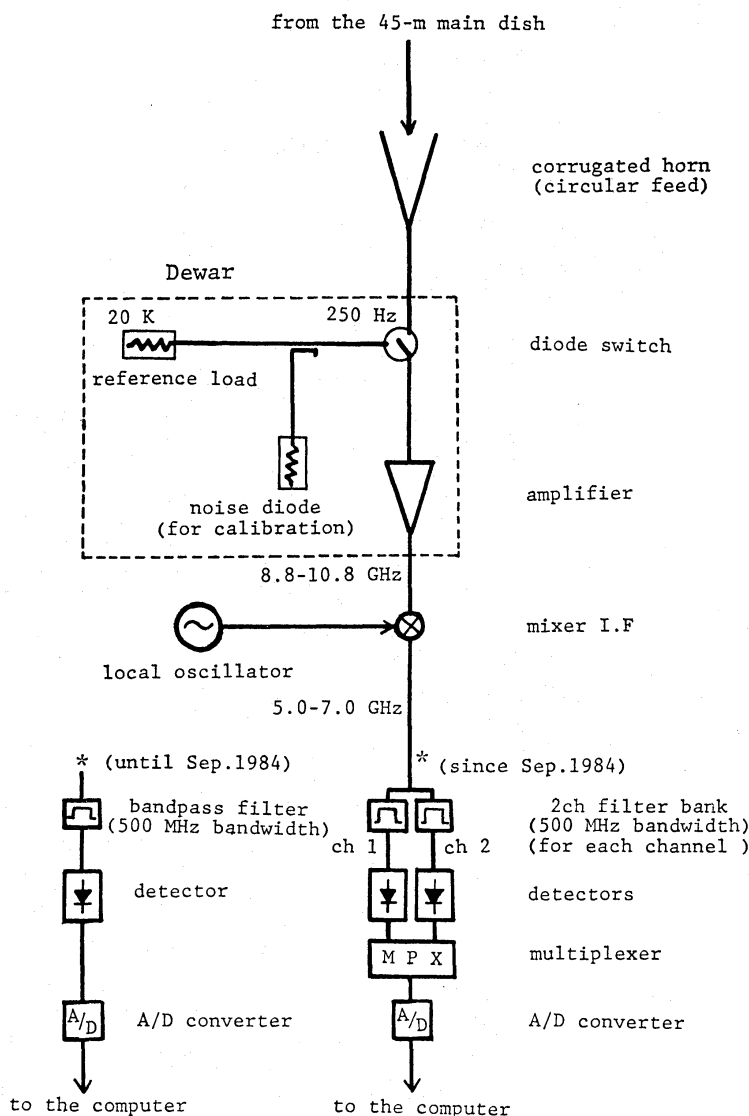

Fig. 2. The 10-GHz receiving system used at the NRO 45-m telescope.

The total intensity was obtained by using a circularly polarized feed and assuming that the circular polarization of the radiation is negligibly small.

The source NGC 7027 was used as the primary calibrator for flux density, and was assumed to be 6.65 and 6.61 Jy at 10.05 and 10.55 GHz, respectively, based on the spectrum of Andrew et al. (1981). The sources 3C 348, 3C 48, and 3C 123 were used as the flux calibrators until June 1983. The flux density of 3C 48 was assumed to be 2.82 Jy at 10.05 GHz based on the spectrum of Andrew et al. (1981). The peak flux density of 3C 348 was assumed to be 4.10 Jy/beam at 10.05 GHz using the NRO 45-m telescope (H. Tabara and T. Kato, private communication). The flux density of 3C 123 was assumed to be 7.94 Jy at 10.55 GHz based on the spectrum of Andrew et al. (1981).

The receiver gain fluctuation in a time scale of 10–20 min was calibrated by measuring the intensity of a standard noise diode.

Figure 2 shows a block diagram of the receiver system of the 45-m telescope. The

receiver consists of cooled parametric amplifiers followed by FET amplifiers.

3. Data Reduction

The first stage reduction was performed by using the CONDUCT system. This is a standard data reduction system for continuum observations at NRO on a FACOM M380S computer. A part of the CONDUCT system uses the NOD2 subroutine package (Haslam 1974). The CONDUCT system will be described in a separate paper.

For maps with a scan length $3^{\circ}0-4^{\circ}0$, both ends of each scan were assumed to be zero level. Then the element maps were checked by inspection to see whether or not emission at either end of the scans is really negligible. If any source exists, then the new base level was set by linear interpolation between the two lowest intensity points along the scan. Finally the PRESS method (Sofue and Reich 1979) was applied to suppress the scanning effects.

For maps with a scan length $2^{\circ}0-2^{\circ}14$, base levels were set using the maps made by combining the maps with a scan length $3^{\circ}0-4^{\circ}0$. The survey map was combined with all these element maps weighted by the inverses of the squares of the noise levels, and was constructed to have a $0^{\circ}02$ square grid referred to galactic coordinates. The final map was convolved by a Gaussian beam as if observed with $3^{\circ}0$ beam to improve the signal to noise ratio. After the convolution the rms noise level of the map is 10–40 mK in T_B (typically 15 mK). The conversion factor from flux density to brightness temperature T_B is $0.356 \text{ K}=1 \text{ Jy}/3^{\circ}0 \text{ beam}$.

4. Results

a. Contour Maps of the Survey

In figures 3 to 33 the 10-GHz survey maps are shown in the form of contour maps of $2^{\circ}2 \times 3^{\circ}$ with 1° grids of galactic and equatorial coordinates (epoch 1950.0). The contour levels are as follows:

- 0.10 K to 1.00 K in 0.10 K step,
- 1.00 K to 3.00 K in 0.20 K step,
- 3.00 K to 5.00 K in 0.50 K step,
- 5.00 K to 10.00 K in 1.00 K step,
- 10.00 K to 20.00 K in 2.00 K step,
- 20.00 K to 50.00 K in 5.00 K step.

Some contours are labeled in relative brightness in kelvins or arrows which point towards local brightness minima. The contours without labels are not drawn where the contours are overcrowded. Notes to the individual maps are given in the captions of each figure.

b. A List of Small Diameter Sources

In table 2 we have listed 144 small-diameter radio sources detected in the survey area. The criteria for including the listed sources are as follows: (1) The apparent diameter at the full width of half maximum is smaller than $4^{\circ}5$ and larger than $2^{\circ}4$ (with $3^{\circ}0$ -beam). (2) The peak flux density is brighter than $0.3 \text{ Jy}/3^{\circ}0 \text{ beam}$. (3)

Fig. 3. The atlas of contour maps in galactic coordinates ordered by decreasing longitude. The labels on contours indicate brightness temperatures in kelvins. The region $l \geq 56^{\circ}1$ has not been observed. The noise level of this map is about 30 mK. Many weak features presented by the lowest contour may not be real.

Fig. 4. See the caption of figure 3. The noise level of this map is about 20 mK. Many weak features presented by the lowest contour may not be real.

Fig. 5. See the caption of figure 3. The noise level of this map is about 25 mK. Many weak features presented by the lowest contour may not be real.

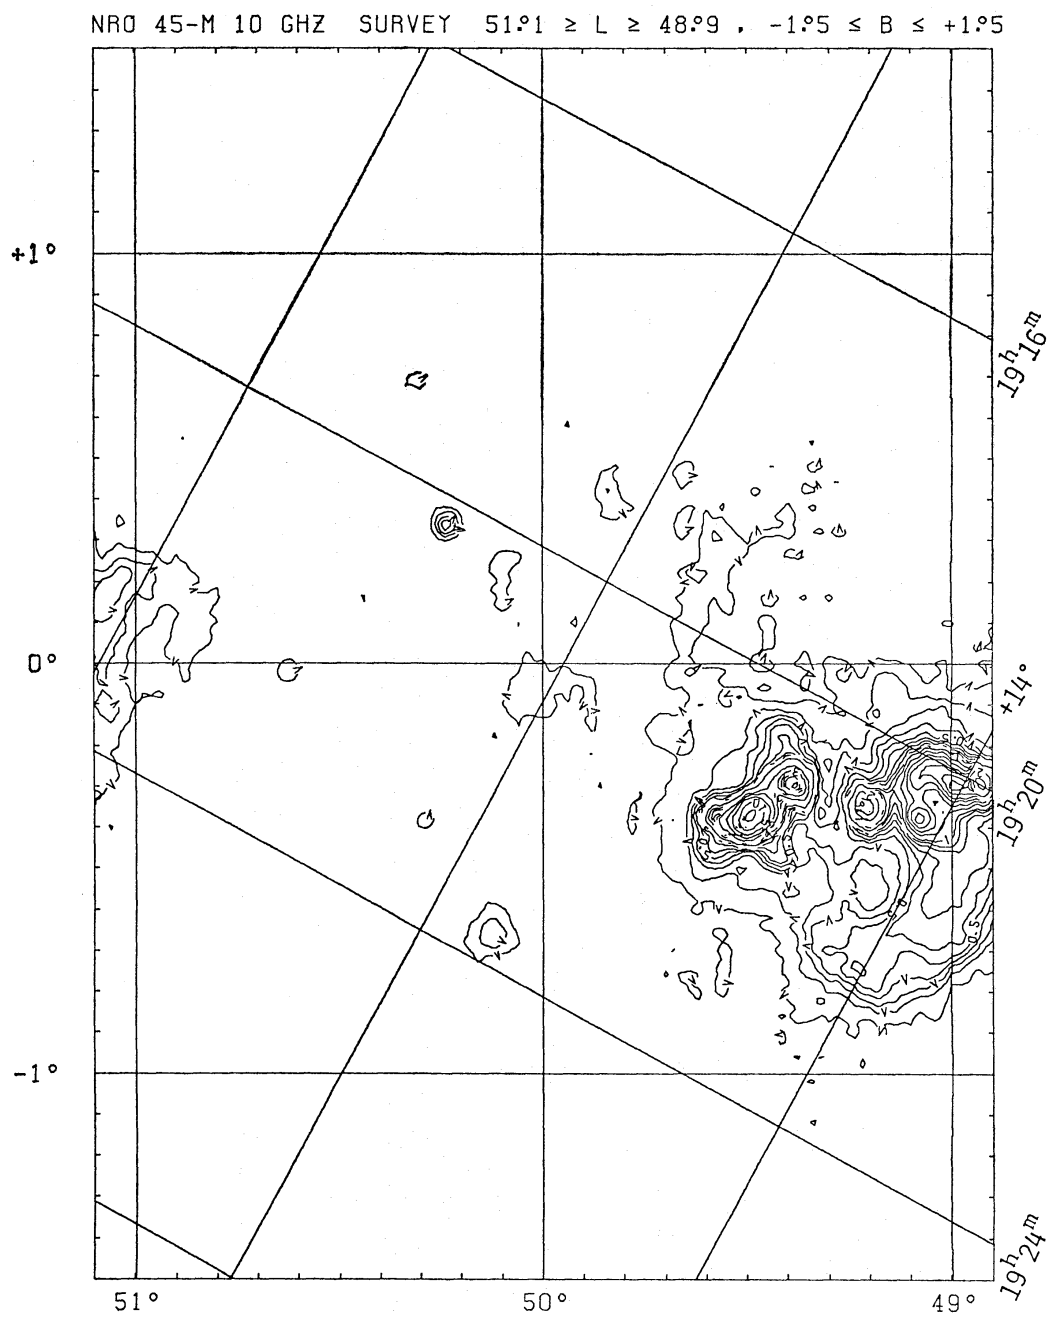

Fig. 6. See the caption of figure. 3 The noise level of this map is about 20 mK. Many weak features presented by the lowest contour in the region near $l \approx 49^{\circ}4$ may not be real.

Fig. 7. See the caption of figure 3.

Fig. 8. See the caption of figure 3. The noise level of this map is about 20 mK. Many weak features presented by the lowest contour may not be real.

The root mean square of the residual values after the fitting is less than 15% of the peak intensity.

The positions, peak flux densities, and sizes of the sources were derived by a Gaussian fitting procedure. A single, round-shaped, two-dimensional Gaussian surface superposed on an inclined plane was applied to a properly selected small area of 7'.6 square around each source.

The column entry to table 2 is explained below:

Column 1: Serial number.

Columns 2 and 3: Galactic longitude and latitude.

Columns 4 and 5: Right ascension and declination for epoch 1950.0.

Column 6: Peak flux density in Jy/3'.0 beam.

Column 7: Apparent diameter at the full width of the half maximum (HPBW=3'.0). Designation P indicates a pointlike source with size smaller than 3'.0.

Column 8: Integrated flux density in units of jansky using the parameters of columns 6 and 7.

Column 9: The base level derived from the fitting in kelvins (T_B). Note that some sources in complex regions may not take proper levels because of the complicated background emission.

Column 10: If an asterisk is marked on the column, the root mean square of the residual values after the fitting is greater than 0.3 Jy/3'.0 beam. In this case the shape of the source may be deviated from the Gaussian distribution and its parameters may be invalid.

Columns 2, 3, 6, and 7 give also the mean errors of each entry on the second line.

The authors acknowledge K. Akabane of NRO for his continuous encouragement and his support during all stages of this project. They also acknowledge the staff of NRO for help in the observations. Especially, they would like to thank K. Miyazawa of NRO for maintaining the 10-GHz receiver. They would like to thank E. Fürst, W. Reich, and P. Reich of Max-Planck-Institut für Radioastronomie for the help in developing reduction software and S. Kobayashi of the Advanced Information Design Co. for developing the display system at NRO. They also thank H. Tabara and T.

Kato of Utsunomiya University for their advice about intensity calibration and encouragement. They would like to thank the referees for improving the English expression and useful advice.
